43 **ABSTRACT**

44 Digital soil mapping (DSM) involves the use of georeferenced information and statistical
45 models to map predictions and uncertainties related to soil properties. Many remote regions of
46 the globe, such as boreal forest ecosystems, are characterized by low sampling efforts and
47 limited availability of field soil data. Although DSM is an expanding topic in soil science, little
48 guidance currently exists to select the appropriate combination of statistical methods and model
49 formulation in the context of limited data availability. Using the Canadian managed forest as a
50 case study, the main objective of this study was to investigate to which extent the choice of
51 statistical method and model specification could improve the spatial prediction of soil properties
52 with limited data. More specifically, we compared the cross-product performance of eight
53 statistical approaches (linear, additive and geostatistical models, and four machine-learning
54 techniques) and three model formulations ("*covariates only*": a suite of environmental covariates
55 only; "*spatial only*": a function of geographic coordinates only; and "*covariates + spatial*": a
56 combination of both covariates and spatial functions) to predict five key forest soil properties in
57 the organic layer (thickness and C:N ratio) and in the top 15 cm of the mineral horizon (carbon
58 concentration, percentage of sand, and bulk density). Our results show that 1) although strong
59 differences in predictive performance occurred across all statistical approaches and model
60 formulations, spatially explicit models consistently had higher R^2 and lower RMSE values than
61 non-spatial models for all soil properties, except for the C:N ratio; 2) Bayesian geostatistical
62 models were among the best methods, followed by ordinary kriging and machine-learning
63 methods; and 3) comparative analyses made it possible to identify the more performant models
64 and statistical methods to predict specific soil properties. We make modeling tools and code

65 available (e.g., Bayesian geostastical models) that increase DSM capabilities and support
66 existing efforts towards the production of improved digital soil products with limited data.

88 **HIGHLIGHTS:**

- 89 • Little guidance exists for selecting statistical models and methods in DSM with limited data.
- 90 • We performed quantitative comparisons among a range of statistical models and methods.
- 91 • Spatially explicit statistical models usually performed better than non-spatial models.
- 92 • Bayesian geostatistical models performed the best, followed by ordinary kriging and machine-
- 93 learning methods.
- 94 • Our study provides modeling tools and guidance that further improve DSM capabilities.

111 **1. Introduction**

112 Spatially explicit soil information is required to assess potential land use, predict
113 vulnerabilities and implement biogeochemical models forecasting the impact of human activity
114 and climate change on terrestrial ecosystems, as well as on the services they provide (Adhikari
115 and Hartemink, 2016; Folberth et al., 2016). Considerable efforts have been made by the
116 research community to harmonize and define common specifications of soil data sets from
117 different origins (Arrouays et al., 2014). These efforts have led to the creation of large soil pedon
118 databases that facilitate the mapping, monitoring and modeling of ecosystem processes at
119 multiple spatial scales, making it possible to predict vegetation shifts (Kuhn et al., 2015) and
120 changes in ecosystem productivity (Maire et al., 2015). Key outcomes of these advances
121 culminated in the release of soil raster products at continental (Hengl et al., 2015) and global
122 (Hengl et al., 2014) scales, together with quantitative estimates of uncertainty associated with
123 predicted soil properties. The availability of soil quantitative estimates is a significant step
124 toward integrating soil indicators into the assessment of ecosystem function and vulnerability
125 (Folberth et al., 2016).

126 Digital soil mapping (DSM) involves the use of numerical methods to fit and validate
127 statistical models on georeferenced soil information (dependent variables) using environmental
128 covariates (independent variables) that represent soil-forming factors, and to map predictions and
129 their uncertainty at a specified spatial resolution over a focal study area. Environmental
130 covariates are obtained from various sources, including remote sensing products and digital
131 elevation models (McBratney et al., 2003). When detailed expert-based soil maps are available,
132 techniques of spatial disaggregation of polygon information are often used (Bui and Moran,
133 2001; Lamboni et al., 2016). However, over large regions, and more typically in forested regions,

134 expert-based soil maps are often unavailable and the *scorpan* model approach (see McBratney et
135 al., 2003), which matches environmental covariates with soil point data (pedons), is commonly
136 used. A key challenge in DSM is that there is almost always a shortage of soil pedon data, which
137 may lead to low model accuracy and/or misrepresentations of predicted soil attributes (Ahrens et
138 al., 2008). How to make the maximum use of sparse data is thus a recurrent challenge in soil
139 science. At the same time, this challenge offers a growing opportunity to develop new statistical
140 approaches that improve soil predictive mapping.

141 Canada's forests, which cover over 390 million ha of land and represent 10% of the
142 world's forest cover, are representative of this situation since only limited soil pedon database are
143 available at the national level. Over the last decades, the pool of available numerical methods
144 and statistical models combined with an increase in computing power and data availability have
145 tremendously boosted DSM capabilities with limited data (McBratney et al., 2003; Grunwald,
146 2009; Brevik et al., 2016). Various new modeling tools are now freely available to predict and
147 map soil types as well as continuous or discrete soil properties. The quality of these predictive
148 soil maps, however, remains highly variable and depends of the interplay among four main key
149 components: 1) the availability and quality of the data for both soil profiles and environmental
150 covariates; 2) the inherent variation in nature complexity and heterogeneity of any focal soil
151 property across spatial scales and soil depth; 3) the specification of statistical models (e.g., the
152 choice of covariates, with linear vs non-linear effects, with simple vs interaction effect terms,
153 with hierarchical structures or not, with the inclusion or not of a spatial component); and 4) the
154 choice of statistical framework (e.g., Bayesian vs frequentist), statistical method and algorithm to
155 fit these models (see Fig. 1), hereafter referred as 'statistical methods'.

156 Machine-learning techniques, in particular, have become very popular in predictive
157 modeling (Hastie et al., 2009; Kuhn and Johnson, 2013), especially in DSM where numerous
158 studies use random forests (Grimm et al., 2008), boosted regression trees (Grinand et al., 2008),
159 *k*-nearest neighbors (Mansuy et al., 2014), Cubist (Rizzo et al., 2016), support vector machines
160 (Were et al., 2015), and artificial neural networks (Behrens et al., 2005). In addition the choice of
161 of statistical method, the choice of statistical models (model specification) includes the use of
162 non-spatial vs spatially explicit models. When the geographical locations of sample plots are
163 recorded, spatially explicit models are often used to account for spatial autocorrelation in the
164 data or in model residuals (McBratney et al., 2003; Dormann et al., 2007; Hengl 2009; Beale et
165 al., 2010; Banerjee et al., 2014), which often improves the accuracy of predictions as well as the
166 predictive performance of the models (Beguin et al., 2012).

167 Although every spatial statistical method has its intrinsic way of modeling spatial
168 correlation structure in the data (Li and Heap, 2014), the following are the most common in
169 practice: 1) using additional covariates that are parametric or non-parametric functions of the
170 sample geographic coordinates, such as in trend surface analyses with linear or additive models
171 (Dormann et al., 2007), in spatial filtering regression (e.g., Moran Eigenvectors; Dray et al.,
172 2006) or in autocovariate regression (Dormann et al., 2007); 2) using spatial covariance structure
173 in the variance-covariance matrix with parametric function (e.g., variograms), such as in
174 generalized least squares (GLS) models (Dormann et al., 2007) or in regression-kriging (Hengl et
175 al., 2004); 3) using weighted matrices of interactions among neighboring sites, such as in
176 conditional (CAR) and simultaneous (SAR) autoregressive models (Banerjee et al., 2014); and 4)
177 using Bayesian hierarchical models where effects of the covariates, spatial effects and nugget
178 effects are combined in an additive model (Banerjee et al., 2014). Bayesian methods may be

179 computationally heavy, but there has been much recent development that makes them readily
180 usable for data sets of realistic sizes of an order of 10000 points and bigger (Sun, et al., 2012,
181 Lindgren and Rue, 2015).

182 While great efforts by the soil mapping community have led to standardized technical
183 specifications regarding the spatial entity, the assessment of soil properties to be predicted, and
184 the handling of uncertainties in DSM (Arrouays et al., 2014), less work has been done to
185 compare the relative performance of a range of statistical methods and model specifications (e.g.,
186 spatial vs non-spatial) across multiple soil properties. Most DSM studies (but see Heung et al.,
187 2016) use one or a few statistical approach(es) (Poggio et al., 2013; Nawar et al., 2015), typically
188 with one type of model specification to analyze specific soil data sets, which often makes unclear
189 the extent to which the combination of particular statistical approach and model formulation
190 influences the outcome.

191 The main objective of this study was therefore to investigate to what extent the choice of
192 statistical methods and model specification could improve the spatial prediction of forest soil
193 properties with sparse soil data. More specifically, we compared the cross-product performance
194 of eight statistical methods (linear, additive and geostatistical models, and four machine-learning
195 techniques) and three different model specifications ("*covariates only*": model fitted with a suite
196 of environmental covariates only; "*spatial only*": model fitted with only a spatial component
197 derived from geographic coordinates of the plots; and "*covariates + spatial*": model fitted with
198 both covariates and a spatial component) to predict five key forest soil properties (thickness and
199 C:N ratio in the organic layer as well as carbon concentration, percentage of sand, and bulk
200 density in the top 15 cm of the mineral horizon).

201

202 **2. Material and methods**

203 *2.1. Study area*

204 The study area covers 290 million ha of managed forests across Canada and extends from
205 52° to 138° West and from 42° to 60° North (Fig. 2). The study area encompasses broad
206 geographical gradients of topography, climate and vegetation (see details in Table 2) that
207 influence soil formation. To predict soil properties and compare results from different models,
208 we used a standardized data set of georeferenced soil pits (pedon) composed of ~500
209 georeferenced ground plots from Canada's National Forest Inventory (NFI; Gillis et al., 2005;
210 Fig. 2). This field soil data set is similar to the one used in Mansuy et al. (2014). Our analysis
211 focused on upland forests and therefore did not cover areas dominated by wetlands and non-
212 forested areas (e.g., agricultural lands).

213

214 *2.2. Soil data and environmental covariates*

215 NFI soil data have the advantage of having been sampled using a standard methodology
216 across Canada, making it representative of broad ecological conditions across the country.
217 However, with about 500 points spaced out at least 20 km apart, NFI data have the disadvantage
218 of being very sparsely distributed at the national scale. Soil properties in each sample were
219 measured, recorded by depth classes, and analyzed in the laboratory according to standard
220 protocols (Gillis et al., 2005). Among the soil attributes available in the database, we selected
221 five soil properties, both in the organic layer and in the top 15 cm of the mineral horizon, that are
222 commonly used as ecological indicators in natural resources management projects (Table 1).
223 Mean, range, and coefficient of variation associated with each of the five selected soil properties
224 are described in detail in Mansuy et al. (2014). For the statistical analysis, the soil data base was

225 randomly split at the beginning of the modeling process to create a training data set and an
226 independent validation data set (Figs. 2 and 3). We tested different training-validation hold-out
227 size combinations (90%-10%; 80%-20%; 70%-30%), but as we did not observe any difference
228 among these combinations, we retained a 90%-10% hold-out partitioning.

229 We related field soil properties to 12 environmental covariates usually associated with
230 soil formation as per the *scorpan* approach (Table 3). We first generated environmental
231 covariates from a digital elevation model and from spatial climate models at a 250 m resolution.
232 We retained four different topographic variables derived from the USGS/NASA SRTM 250 grid
233 map (<https://www.usgs.gov>) (Table 3). We also used six climate variables derived from the
234 spatial climate models of McKenney et al. (2011). For vegetation composition, we used derived-
235 MODIS maps of the proportion of coniferous and deciduous species (Beaudoin et al., 2014). We
236 also tested the use of the surficial geology map of Canada (Geological Survey of Canada,
237 geogratis.gc.ca) as predictor, but because of a lack of explaining power, these attributes were not
238 retained in the final analyses. We did not use soil classification maps as predictors because of
239 their high uncertainty in Canadian boreal forests and because of the low sample size per soil
240 class. All environmental predictors were raster layers projected into Canada's Lambert
241 Conformal Conic with a spatial resolution of 250 m (1 pixel = 6.25 ha), and covered the entire
242 land base of Canada's managed boreal forest (Table 3).

243

244 *2.3. Statistical methods*

245 We compared the predictive performance of eight different statistical approaches,
246 including two parametric methods (linear and additive models), four non-parametric methods of
247 machine learning (boosted regression trees, random forests, Cubist and weighted *k*-nearest

248 neighbors), ordinary and regression kriging, and one method of Bayesian inference with
249 geostatistical models fitted with the method of integrated nested Laplace approximation (INLA)
250 (Fig. 3). Justification for the choice of these methods is as follows: 1) except for Bayesian
251 geostatistical models, these methods encompass the majority of statistical routines currently used
252 in DSM studies; 2) they include algorithms that are known to be efficient in predictive modeling;
253 3) they encompass a gradient of complexity; and 4) they can handle spatial dependence
254 structures in various ways (Li and Heap, 2014). Although we acknowledge that our selection of
255 methods is not exhaustive, these methods are representative of the ones used in DSM studies and
256 they suit the purpose of this study. For parametric approaches, we used generalized linear (GLM)
257 and additive (GAM) models. For machine-learning approaches, we selected four supervised
258 methods that are used extensively in predictive modeling (Kuhn and Johnson, 2013). Supervised
259 learning encompasses a wide range of optimized algorithms designed to uncover patterns in
260 training data, with the primary objective of making accurate predictions based on independent
261 data (Hastie et al., 2009).

262 Among the four selected machine-learning methods, we retained two ensemble modeling
263 techniques: random forests (RF) (Breiman, 2001) and boosted regression trees (BRT) (Friedman,
264 2001, 2002). Both techniques accommodate a variety of response types and efficiently deal with
265 missing data and outliers, interactions among predictors, and non-linear relationships between
266 predictors and the response variable. RF uses a modified bootstrap aggregation (bagging)
267 algorithm (e.g., Breiman's algorithm) that fits a high number of independent classification trees
268 on random subsamples of the original data set (Breiman, 2001). Model predictions are then
269 estimated as weighted averages across all trees. Weights are calculated according to the
270 predictive performance of each tree, which ensures that the best trees contribute the most to final

271 predictions (Hastie et al., 2009). RF differs from other decision tree methods in that each
272 regression tree is fitted with a different random subset of covariates based on random subspace
273 techniques (Ho, 1998). We performed extensive sensitivity analyses on two key parameters: the
274 maximum number of trees and the number of predictors for each tree. More information on the
275 theoretical and practical aspects of RF can be found in Breiman (2001), Liaw and Wiener (2002),
276 and Hastie et al. (2009).

277 BRT combines large numbers of regression tree models adaptively to optimize predictive
278 performances (Friedman, 2002) and differs from other decision trees techniques by using a
279 boosting algorithm (e.g., AdaBoost: Freund and Schapire, 1996). The purpose of a boosting
280 algorithm is to minimize a loss function averaged over random training data sets and to seek by
281 the use of successive iterations, to improve predictions on poorly fitted data points (see Elith et
282 al. (2008) for more details). BRT requires more tuning than RF and we performed extensive
283 sensitivity analyses on four key parameters: tree complexity or interaction depth (*tc*), learning
284 rate or shrinkage parameter (*lr*), number of trees (*nt*), and minimum number of observation in
285 nodes (*minobs*) (see also Appendix 1.1). A full description of these parameters is beyond the
286 scope of this study, but detailed information can be found in Elith et al. (2008) and Kuhn and
287 Johnson (2013).

288 The third machine-learning method used in this study is Cubist, a rule-based regression
289 technique developed by Quinlan (1992, 1993), which fits a separate multiple linear model at each
290 leaf node of a regression tree according to a set of conditional rules (Walton 2008). These rules
291 have the form of conditional logical statements (*if... then...*) and divide the training data set into
292 multiple subsets, where each subset is composed of data points sharing common statistical
293 properties. A regression model is then fitted separately for each rule/subset. In contrast with

294 other tree methods, Cubist allows for more than one conditional statement to be combined at
295 each intermediate leaf node of a tree. Predictions are then made based on the match with a rule's
296 condition and its associated regression model. To improve prediction accuracy, Cubist can be
297 coupled with a bootstrap aggregation algorithm (committees > 1), where the number of
298 committee models defines the number of boosting iterations. In addition, Cubist can incorporate
299 composite instance-based models by varying the number of nearest neighbors. More details on
300 Cubist and these options can be found here: www.rulequest.com. We performed sensitivity
301 analyses on two key parameters: the number of committees and the number of nearest neighbors
302 (see also Appendix 1.1).

303 The last machine-learning method we tested is derived from the k -nearest neighbors (k -
304 NN) method (Cover and Hart, 1967). The k -NN method is based on the assumption that the more
305 two observations are similar regarding their range of values for a set of independent variables,
306 the more their predicted values for a response variable of interest should be close. Predicting
307 values for a new observation can therefore be made by using the sampled observations from a
308 training data set that are the closest (= nearest neighbor(s)) to each new observation with respect
309 to the covariates used (not to be confused with nearest neighbors in geographic space).
310 Determination of the similarity between new and training samples is based on distance metrics,
311 and the method has been expanded to a set (k) of nearest neighbors. The weighted k -NN
312 (KKNN) method extends k -NN by adding the characteristic that sample points within the
313 training data set that are particularly similar to the new observation should have more weight in
314 the decision than neighbors that are further away from it (Hechenbichler and Schliep, 2004). The
315 KKNN method used in this study fits kernel functions to weigh nearest neighbors according to
316 their similarity distance from each new data point, and uses these weights in combination with

317 covariates to make predictions. For each predicted soil variable, we performed sensitivity
318 analyses on both the type of kernel function for weighing neighbors and the optimal maximum
319 number (= k) of nearest neighbors (see also Appendix 1.1).

320 In a Bayesian linear geostatistical model, the dependent variable is described as an
321 additive combination of latent explanatory components, such as linear effects of independent
322 variables, a spatial effect indexed by the geographical locations, and a nugget effect representing
323 a discontinuity from the semi-variogram at its origin. The main advantages of such a model over
324 the machine-learning methods are 1) the interpretability gained by an explicit model as to how
325 observations are generated; and 2) in the Bayesian framework, uncertainty estimates are directly
326 available for all parameters as well as for predictions. The disadvantages of Bayesian methods
327 are that they can be difficult to implement and are computationally expensive to run. The INLA
328 methodology (Rue et al., 2009) combined with the recent stochastic partial differential equation
329 (SPDE) approach to spatial fields (Lindgren et al., 2011), provides a methodological solution to
330 these limiting factors. Moreover, the INLA R-package makes them easy to use (Lindgren and
331 Rue, 2015). The main difference between the INLA methodology and the standard use of
332 Markov Chain Monte Carlo (MCMC) simulations is that INLA is not based on sampling, but
333 rather on deterministic approximations to integrals, which makes it computationally quicker than
334 MCMC approaches, while still being very accurate (Rue et al., 2009).

335

336 *2.4. Model specifications*

337 To evaluate if patterns of spatial autocorrelation among sample plots could be used as
338 surrogates for unmeasured covariates and contribute to explaining more residual variation in soil
339 properties than the variation explained by environmental covariates alone, we fitted and

340 compared, for each statistical method, three different statistical model specifications (Fig. 3): 1) a
341 first type of model (labelled "*covariates only*") that uses only environmental covariates
342 (topography, vegetation, and climatic conditions) as predictors. This type of model is non-spatial
343 because no explicit spatial relationships among sample plots are quantified; 2) a second type of
344 model (labelled "*spatial only*") that only uses a spatial component, i.e. a function of the
345 geographic coordinates of sample plots (latitude and longitude), to predict soil properties. Note
346 that the specification of spatial functions differs for each statistical method (see section 2.5.).
347 However, all "*spatial only*" models share the characteristic that they only consider spatial
348 locations and distances among plots to predict and map soil properties; 3) the last type of model
349 (labelled "*covariates + spatial*") is a combination of the two first types, in which soil properties
350 are predicted as a function of both environmental covariates and a spatial component that
351 quantifies possible spatial relationships among sample plots.

352

353 2.5. Spatially explicit models

354 As the way of quantifying spatial relationships among sample plots varies according to
355 the statistical method used, we used method-specific spatial functions in the "*spatial only*" and
356 "*covariates + spatial*" models that belong to one of these three classes: kriging, stochastic partial
357 differential equations, or models that use a function of spatial coordinates (latitude + longitude)
358 of sample plots directly as predictors. For kriging, we compared local ordinary kriging, and
359 regression kriging both fitted with an exponential variogram model. We assumed stationarity and
360 isotropy in all cases. For local ordinary kriging ("*spatial only*" model), we set the maximum
361 number of nearest neighbors to 20. In regression kriging ("*covariates + spatial*" model), a
362 regression model was first fitted to the data using environmental covariates as predictors, and

363 ordinary kriging was performed in a second step on the model's residuals (Hengl et al., 2004).
364 Kriged residuals were then added to the predictions of the regression model. In this study, we
365 compared two regression kriging methods: one in which the relationship between each soil
366 property and environmental covariates is evaluated through a GLM (Hengl et al., 2014), and the
367 other in which the relationship between each soil property and environmental covariates is
368 evaluated through the RF algorithm (Hengl et al., 2015).

369 For spatial GAMs, we modelled spatial relationships as covariates using a trend-surface
370 obtained from a two-dimensional spline function on geographical coordinates (Dormann et al.,
371 2007). In addition to the RF-kriging described above, we fitted another spatial RF model using
372 the geographical coordinates of soil samples directly as predictors along with the other
373 environmental covariates. As the RF algorithm automatically evaluates interactions among
374 covariates, the use of geographical coordinates as covariates allowed us to account for possible
375 latitudinal and/or longitudinal gradients in the effect of environmental covariates on soil
376 properties. We used the same approach, with the inclusion of geographical coordinates of the
377 samples as predictors, for BRT, Cubist, and KKNN. For completeness and comparative
378 purposes, we fitted a linear model with only the latitude and longitude of the sample plots as
379 simple and linear effect.

380 For Bayesian geostatistical models, we used INLA together with the SPDE approach
381 proposed by Lindgren et al. (2011), where the spatial field is described as the solution to a linear
382 differential equation driven by white noise and involves the construction of meshes on which the
383 spatial field is defined (see Blangiardo and Cameletti, 2015; Appendix 1.3). With the Bayesian
384 framework, priors need to be defined for each parameter of the model. We used non-informative
385 default priors for coefficients of the environmental covariates, and a weakly informative prior for

386 the spatial effect (Fuglstad et al., 2015; see Appendix 1.3 for the definition of priors associated
387 with the spatial effect and the variance of the nugget effect). Overall, the mixture of eight
388 statistical methods and three different model specifications yielded a total of 24 unique method-
389 model combinations for each soil property (see Fig. 4).

390

391 2.6. Evaluation of predictive performances

392 All models were calibrated on 90% of the soil data base using cross-validation and
393 validated on the remaining 10% of the soil data base (see Fig. 3). To address the fundamental
394 trade-off between model complexity and prediction errors on independent data sets (see p. 220 in
395 Hastie et al., 2009), we pruned all our models during the calibration stage and only retained
396 relevant environmental covariates that minimized root mean square error (RMSE) values using
397 repeated 10-fold cross-validation. We made sure that comparisons among the three types of
398 model ("*covariates only*", "*spatial only*", and "*covariates + only*") for each statistical method
399 were valid by retaining the same set of environmental covariates for every predicted soil property
400 (see Table 1). For all models, we calculated the coefficient of determination (R^2) and RMSE
401 using 10-fold cross-validation repeated 20 times (see Fig. 3) (Bennett et al., 2013). This standard
402 procedure prevented our analyses from having overfitting issues, while providing fair estimates
403 of prediction errors (Hastie et al., 2009). Cross-validated R^2 was calculated as $R^2 = 1 - \text{ESS}/\text{TSS}$,
404 where:

$$405 \quad \text{ESS} = \sum_i (y_{i(\text{observed})} - y_{i(\text{predicted})})^2$$

$$406 \quad \text{TSS} = \sum_i (y_{i(\text{observed})} - \bar{y}_{(\text{observed})})^2$$

407 We report the quantile distribution (0.025%, 50%, and 97.5%) of cross-validated R^2 and
408 RMSE calculated from 20 runs, which gives us information on the variation in mean cross-

409 validated R^2 and RMSE across repetitions. We reported cross-validated RMSE values as
410 percentages of the sample mean ($\text{RMSE} (\%) = 100 \times \text{RMSE}/\bar{y}$). Finally, to ensure independent
411 validation, we validated all our models in calculating independent R^2 between predictions from
412 cross-validated models with observed values from independent data (Figs. 3 and 5). All models
413 were run in the R environment (R Core Team, 2015). INLA was run using the ‘*R-INLA*’ package
414 (Rue et al., 2009), ordinary kriging was fitted using the ‘*gstat*’ package (Pebesma and Graeler,
415 2013), and we used the ‘*GSIF*’ package for regression-kriging and RF-kriging (Hengl et al.,
416 2016). All other statistical methods and models were run using the ‘*caret*’ meta-package (Kuhn,
417 2015) in combination with the following R packages: ‘*gbm*’ (Ridgeway 2015: BRT),
418 ‘*RandomForests*’ (Liaw 2015), ‘*Cubist*’ (Kuhn et al., 2015), ‘*kknn*’ (Schliep and Hechenbichler,
419 2015), and ‘*mgcv*’ (Wood, 2015; GAM). All R-codes used to run our analyses are available in
420 Appendix 1.

421

422 **3. Results**

423 *3.1. Performances of statistical methods and models*

424 Our comparative analyses revealed that the choice of the statistical method, the type of
425 model specification ("*covariates only*", "*spatial only*", or "*covariates + spatial*"), or their
426 interaction significantly influenced the predictive performance for most soil properties tested in
427 this study (Figs. 4 and 5). For instance, cross-validated R^2 and RMSE values of non-spatial
428 models for sand content (%) were respectively over 100% higher and lower when using either
429 RF or BRT (median cross-validated R^2 ranging from 0.23 to 0.28; Fig. 4) than when using either
430 linear or additive models (median cross-validated R^2 ranging from 0.04 to 0.13; Fig. 4). On the
431 other hand, the best cross-validated R^2 and RMSE values of "*spatial only*" models for sand

432 content were obtained with INLA/SPDE, followed by ordinary kriging and machine-learning
433 techniques (median cross-validated R^2 ranging from 0.38 to 0.46; Fig. 4). For "*covariates +*
434 *spatial*" models, INLA/SPDE yielded the best predictive performance for sand, followed by
435 machine-learning techniques and linear regression-kriging (Fig. 4).

436 Although strong differences in predictive performance occurred across all statistical
437 methods and model types, models that incorporated a spatial component consistently had higher
438 cross-validated R^2 and lower cross-validated RMSE values than non-spatial models for all soil
439 properties, except for the C:N ratio in the organic layer (Fig. 4). This result indicates that the
440 spatial relationships among soil samples contain valuable information that is not captured by
441 environmental covariates and that the inclusion of spatial information improves the overall
442 predictive performance (Fig. 4). This improvement was also verified on independent data sets
443 (Fig. 5). Interestingly, "*covariates + spatial*" models outperformed "*spatial only*" models for
444 only one soil property, the organic layer C:N ratio (Fig. 4). This result highlights that in most
445 cases in our study, there is a significant redundancy between the variation captured either by
446 environmental covariates or by spatial functions.

447

448 *3.2. Mapping predictions*

449 Mapping the predicted values (mean + standard deviation) from "*spatial only*" or
450 "*covariates + spatial*" models using machine-learning methods with latitude and longitude of
451 soil samples as covariates occasionally generated spatial discontinuities with sudden transition
452 patterns along longitude in predicted surfaces (results not shown). Such prediction artefacts,
453 which could not be detected by analyzing the fit of the model alone, did not occur with spatial
454 models fitted with INLA or with regression kriging. When spatial relationships among soil

455 samples explained a significant part of the total variance (Fig. 4), the spatial distribution of
456 prediction errors also exhibited strong spatial patterns (Fig. 6D for sand), with clusters
457 containing the highest level of uncertainty in areas with low sampling density. Inversely, when
458 the results showed low levels of residual spatial structure, such as for the C:N ratio in the organic
459 layer (Fig. 4), the spatial distribution of prediction errors was more homogeneous across
460 landscapes (see Fig. 6E for the C:N ratio). These results may be used to improve data acquisition
461 strategies.

462

463 **4. Discussion**

464 Our main findings demonstrate that, irrespective of the effects of environmental
465 covariates and of the inherent variation present in soil profile data sets, both the choice of
466 statistical method and the choice of model type can have a significant impact on the predictive
467 performance for most predicted forest soil properties tested in this study. These results are
468 inconsistent with the view that the choice of statistical method and the type of model
469 specification would have a negligible influence on the performance and accuracy of predicted
470 soil maps calibrated with limited soil data. Our study shows that selecting one suboptimal
471 combination of statistical method and model type could lead to a decrease in predictive power as
472 high as 100% and sometimes higher (see Fig. 4). These results have a number of important
473 implications for further work on DSM in a context of limited soil data.

474 Our results indicate that most forest soil properties are characterized by some degree of
475 spatial autocorrelation that may have different degrees of redundancy with the information
476 contained in the environmental covariates available. If the spatial information contained in soil
477 data points overlaps strongly with the one contained in the environmental covariates, including

478 both sorts of information in a same model may lead to unnecessary complexity in the model. As
479 predicted by the bias-variance trade-off, models that are overfitted on training data often have
480 higher prediction errors with independent data (Hastie et al. 2009). Our results on sand, thickness
481 and bulk density are in agreement with these predictions as more complex "*covariates + spatial*"
482 models fitted with machine learning methods often had lower cross-validated and independent R^2
483 (Figs. 4 and 5) than "*spatial only*" models. Interestingly, such a pattern did not occur with the use
484 of the SPDE/INLA approach where either "*covariates + spatial*" or "*spatial only*" models were
485 very similar in terms of predictive performance (see Figs. 4 and 5). At the opposite, if the
486 information captured by spatial functions and environmental covariates is additive and contains
487 low levels of redundancy, a model formulation including both the effects of environmental
488 covariates and an appropriate spatial structure will be useful to decrease prediction errors on
489 independent data. This raises the question as to whether or not spatial models should be
490 systematically tested in DSM exercises when soil pit data are limited? A pragmatic answer
491 would be 'yes', but more studies are needed in this area as the benefits of including spatial
492 correlation structures may also depend on the sampling efforts or the breadth of environmental
493 gradients present in the study area and in the sampled data.

494 Under our study conditions, more specifically a very large land base, a limited number of
495 soil pit data and a high minimal distance between soil pits (> 20 km), "*covariates only*" models
496 outperformed "*spatial only*" models for only one of the soil variables studied: the C:N ratio of
497 the organic layer. Also, only for this soil property did the "*covariates + spatial*" models clearly
498 outperform "*spatial only*" models. A possible explanation for this result is that forest
499 composition, which is known to influence soil C to N stoichiometry (Averill et al. 2014), mostly
500 varies over distances < 20 km because of its strong dependence on local disturbance history

501 (Chen et al., 2009). A distance variation < 20 km could not be captured accurately by the
502 sampling scheme of our data set; hence, the consideration of covariates expressing forest
503 composition appears to bring relevant information that is non-redundant with that captured by
504 the "*spatial only*" models. As for the other soil properties to be predicted, the limited
505 improvement obtained by adding environmental covariates, once spatial information has been
506 taken into consideration, indicates that the environmental covariates considered either
507 contributed little to explaining these soil properties, or that their explaining potential is redundant
508 with the spatial information contained in the data. Such was the case for climate variables that
509 varied over large distances (> 100 km) and contributed to predict several forest soil properties in
510 "*covariates only*" models, but were redundant in "*spatial only*" and "*covariates + spatial*"
511 models once spatial correlation structures had been taken into account. Although it can be
512 challenging to identify which ecological process(es) is(are) the cause(s) of the observed patterns
513 of spatial autocorrelation, the use of spatially-explicit statistical models, together with cross-
514 validation techniques, may at least provide practical alternatives to improve the accuracy of and
515 decrease prediction errors in digital soil maps calibrated with limited data.

516 The digital soil maps obtained with the best model fitted with INLA showed patterns
517 that are consistent with the large-scale gradients observed in existing national soil information
518 products (Canadian System of Soil Classification: <http://sis.agr.gc.ca/cansis/>). For example, the
519 map of sand content (Fig. 6A) highlights the fine texture soils of the Ontario-Quebec Clay Belt
520 region, formed by the draining of the former proglacial Lake Ojibway around 8,200 BP (Vincent
521 and Hardy, 1977), as well as the large offshore glaciolacustrine sediment of northern Manitoba
522 (<http://www.gov.mb.ca/iem/geo/>). The coarse texture soils, abundant in northern Saskatchewan
523 (<http://publications.gov.sk.ca/>) are also apparent. The map of organic layer C:N ratio showed a

524 latitudinal gradient with highest values in the north and lowest ones in the south, which is
525 closely associated with the percentage of coniferous species in the canopy of Canadian forests
526 (Beaudoin et al., 2014). The spatial distribution of bulk density is more complex as it relates to
527 several soil properties, including soil texture, organic matter content, and soil compaction
528 (Sequeira et al., 2014). The use of the most performant models substantially improved the
529 goodness-of-fit obtained from previous national modeling efforts for sand content (+ 131 %),
530 bulk density (+ 105 %), thickness of the organic layer (+ 205 %), and C:N ratio in the organic
531 layer (+ 596 %) (Mansuy et al., 2014).

532 Another implication of our results is that the performance and ranking of modeling
533 strategies may also depend on the property to be predicted, highlighting the need to move beyond
534 the single statistical model–method philosophy for DSM. Clearly, more testing and quantitative
535 comparisons are needed to get a comprehensive picture of the model-method combination that is
536 best in specific situations. A significant step forward would be the completion of a comparative
537 modeling study of soil properties in which the efficiency of a wide range of combinations of
538 statistical methods and model classes would be evaluated over multiple spatial scales, along a
539 gradient of sampling density, and across contrasting ecosystems. It would also be relevant that
540 such a synthesis be expanded to statistical methods not commonly used in soil research. For
541 instance, the use of Bayesian linear geostatistical models consistently yielded some of the best
542 predictive performances across the soil properties tested in this study. Although Bayesian
543 geostatistical models have been used with success in a wide range of applied contexts in
544 environmental sciences (Rue et al., 2016), it is surprising to note that their use in DSM has been
545 very limited so far. As our results point out, this might partly be due to the fact that these models
546 come with an increase in computational time (Appendix 2), require substantial knowledge in

547 programming, and involve a relevant choice of priors. However, technical guides available to
548 non-expert programmers now exist to facilitate the implementation of these types of model
549 (Blangiardo and Cameletti, 2015), and we freely provide all the scripts needed to replicate our
550 analyses with k-fold cross-validation and mapping procedures in the R environment. The free
551 availability of statistical routines to perform comparative analyses in open-access, efficient and
552 repeatable ways opens new perspectives in this area and provides strong capabilities to non-
553 expert programmers or to researchers working in environments where programming expertise is
554 limited.

555

556 **5. Conclusion**

557 Results from our comparative study suggest that better mapping of soil properties may be
558 achieved through quantitative assessment when selecting the statistical method and model
559 specification (spatial vs non-spatial models). Overall, spatially explicit models showed
560 significantly better predictive performance (R^2 and RMSE), with improvements ranging from
561 10% to more than 100% compared with non-spatial models, depending on the soil property.
562 Bayesian geostatistical models fitted with INLA showed among the best predictive performances
563 and mapping properties with our data set. The use of comparative statistical analyses as a
564 standard modeling practice, which goes beyond the single model–statistical method philosophy,
565 would be a valuable asset to increase the development of DSM capabilities. Therefore, this study
566 constitutes a step forward in the improvement of DSM capabilities by providing a quantitative
567 assessment of the performance of a variety of spatial techniques coupled with systematic
568 comparisons with non-spatial models. We provide scripts and suggestions for facilitating the
569 achievement of this standard in applied research communities with limited computational

570 resources and programming expertise. Finally, to avoid overfitting issues and to make
571 comparison among DSM studies possible, we would recommend that the methodology for model
572 calibration and validation in DSM studies be better standardized and applied rigorously, for
573 example, by using repeated k-fold cross-validation.

889 **Table 2.** Description of environmental covariates (rasters with pixel resolution of 250 m x 250
890 m) used to predict each of the five soil properties (see Abbreviations in Table 1) across the
891 boreal forest of Canada.
892

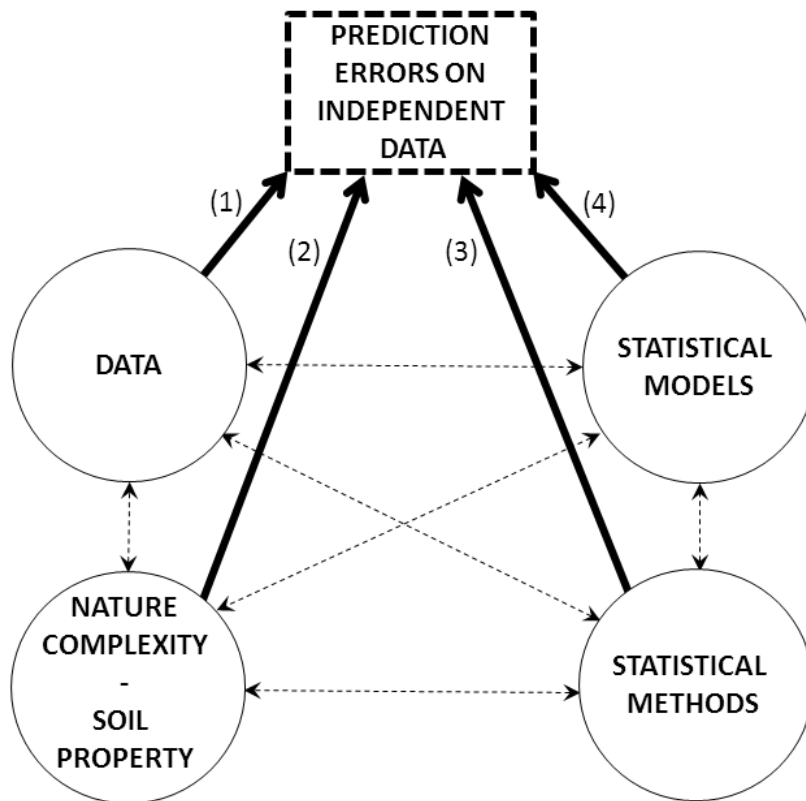

Covariates	Category	Definition	Mean [min;max]	Predicted soil property				
				Sand	C:N	Cmin	Thick-ness	BD
Elevation	topography	Elevation from the Shuttle Radar Topography Mission (m)	563 [0; 3950]	√	√	√	√	√
Slope	topography	Rate of maximum change in elevation from each pixel (%)	4.2 [0; 64.8]				√	
Beers aspect	topography	Heat index = (1+cos(45-Aspect))/Slope	0.99 [0-2]	√				
Watershed structure	topography	Local drainage area enclosed between the local divide and the stream into which each cell drains	483 [-30; 2582]					√
Acmi	climate	Annual moisture index (cm/year)	43 [-127; 385]	√				
Scmi	climate	Summer moisture index (cm/summer)	-2.5 [-76.5; 676]	√				
Pwq	climate	Precipitation of the warmest quarter (mm)	99 [0-796]	√				
Tcm	climate	Lowest temperature of any monthly minimum (°C)	-12.5 [-48.9; 6.1]			√		√
Thm	climate	Highest temperature of any monthly maximum (°C)	11.2 [-4.5; 37.8]					√
Tap	climate	Total annual precipitation (mm)	315 [0; 4302]				√	
Deciduous	vegetation	Percentage of deciduous species in the pixel (%)	19.0 [0; 100]	√	√	√	√	√
Coniferous	vegetation	Percentage of coniferous species in the pixel (%)	58.3 [0; 100]	√	√	√	√

904 **FIGURES**

905 **Fig. 1.** Conceptual framework showing the interrelationships among the four main components
906 that influence predictive errors in digital soil mapping when using statistical approaches. Getting
907 the lowest prediction errors between observed and predicted soil properties on independent data
908 is the main objective of digital soil mapping. Conceptually, the causes of prediction errors can be
909 divided into four main components: (1) the quality and availability of the data (e.g., sample size,
910 quality, spatial resolution and precision); (2) nature complexity or the level of heterogeneity in
911 soil properties; (3) the choice of statistical framework (e.g., Bayesian vs frequentist), statistical
912 method and algorithm, hereafter referred as ‘statistical methods’; and (4) the choice of statistical
913 model (e.g., spatial vs non-spatial, linear vs non-linear effects, simple vs interaction effect
914 terms). Each of these components can act alone (bold arrows) or interact with other components
915 (dashed arrows) to shape the accuracy of digital soil maps.

957

958 **Fig. 3.** Diagram showing the main steps of the modeling process used in this study. The ‘model
 959 specification’ step involves the selection of three different model types: 1) "*covariates only*":
 960 non-spatial models using only environmental covariates (topography, vegetation, and climate
 961 conditions) as predictors; 2) "*spatial only*": spatial models using only a function of the
 962 geographic coordinates of sample plots to predict soil properties. Note that each spatial function
 963 is different and specific to each statistical method (see Fig. 4); 3) "*covariates + spatial*": spatial
 964 models that combine both the effects of environmental covariates and a spatial function as above.
 965 Each of these three model types is fitted with every statistical method/framework (N = 8) at the
 966 ‘selection of statistical method/framework’ step. This process yielded a total of 24 combinations
 967 of model type-statistical method for each soil property. The predictive performances of each of
 968 the 28 combinations are compared using 10-fold cross-validation repeated 20 times. Predictions
 969 are then compared with values observed on independent data.

970

971

972

973 **Fig. 4.** Cross-validated R^2 and root mean square error (RMSE %) (median \pm 95% quantile
974 intervals) for five soil properties using 10-fold cross-validation repeated 20 times. Soil variables
975 of the organic layer: carbon-nitrogen ratio (= C:N ratio organic) and thickness (cm) (= Thickness
976 organic). Soil variables in the top 15 cm of the mineral horizon: bulk density (g/cm^3) (= Bulk
977 density); carbon concentration (g/kg) (= C mineral), and the percentage of sand (= Sand
978 mineral). Values are depicted as a function of the statistical method (y-axis) and type of model
979 used (see colors in the legend). Note that for visual clarity, RMSE quantile values for Thickness
980 organic and C mineral variables have been downscaled by a factor two and three, respectively
981 (see right corner of each panel). Acronyms of statistical methods: INLA = integrated nested
982 Laplace approximation; Kriging = kriging (ordinary or regression-kriging); GLM = generalized
983 linear model; GAM = generalized additive model; Cubist = Cubist algorithm; KKNN = weighted
984 k -nearest neighbors; BRT = boosted regression trees; RF = random forests; SPDE = stochastic
985 partial differential equation approach.
