(Received)

The effect of turbulence on the mass transfer between a fluid and embedded small heavy inertial particles (HIP) that experience surface reactions is studied. For simplicity, the surface reaction, which takes place when a gas phase reactant is converted to a gas phase product at the external surface of the particles, is unimolar and isothermal. Two effects are identified. The first effect is due to the relative velocity between the fluid and the particles, and a model for the relative velocity is presented. The second effect is due to the clustering of particles, where the mass transfer rate is inhibited due to the rapid depletion of the consumed species inside the dense particle clusters. This last effect is relevant for large Damköhler numbers, where the Damköhler number is defined as the ratio of the turbulent and chemical time scales, and it may totally control the mass transfer rate for Damköhler numbers larger than unity. A model that describes how this effect should be incorporated into existing simulation tools that utilize the Reynolds Averaged Navier Stokes (RANS) approach is presented.

Key words: Reacting multiphase flow, Particle/fluid flow, Combustion, Turbulent reacting flows, Turbulence simulations

1. Introduction

Both in nature and in industrial applications, one regularly finds small inertial particles embedded in turbulent flows. By small inertial particles, we mean particles that are smaller than the smallest scales of the turbulence and have significantly higher material density than the fluid. For such particles, there will be momentum exchange between the particles and the turbulent fluid, and, depending on the conditions, there may also be heat and mass transfer. This is particularly so for chemically reacting particles, but there are also a large number of other applications where heat and mass transfer between particles and fluid are important. Here, the main focus will be on reacting particles that consume one or more of the species in the embedding gas through surface reactions. Relevant examples are; chemical reactions on the surface of a catalytic particle, fuel oxidation on the surface of a oxygen carrying particle in a Chemical Looping Combustion (CLC) reactor, condensation of water vapor on cloud droplets and combustion or gasification of char.

The presence of turbulence in a fluid will enhance the transport properties of the flow. This means that the mean-field viscosity, diffusivity and conductivity may be drastically increased from their laminar values. This effect has been studied for many years, and a large number of different models exist in the literature, such as the k- ϵ model (Jones & Launder (1972)) and different versions of the Reynolds Stress Models (e.g. Pope (2003)). Turbulence may also modify gas phase combustion, and even though this is somewhat more complicated, a significant

number of models have been developed during the last decades. Some examples are the Eddy Dissipation Model (Magnussen & Hjertager (1976)), the Eddy Dissipation Concept (Ertesvåg & Magnussen (2000)) and variations of Probability Density Function (e.g. Dopazo (1994)) models.

With the above knowledge in mind, it is interesting to realize that, except for the recent work of Kruger et al. (2017), there is currently no model describing the effect of turbulence on the heat and mass transfer of small inertial particles. When a reacting particle is embedded in a turbulent flow, the turbulence can potentially influence the mass transfer, and hence the surface reaction rates in two ways. The first way is through particle clustering, where particles form dense clusters due to turbulence, and where the gas phase reactants within the cluster are quickly consumed while there are no particles that can consume the reactants in the particle voids outside the clusters. The main effect of the clustering is to *decrease* the overall mass transfer rate. The second way turbulence influence the mass transfer rate is by increasing the mean velocity difference between the particle and the gas. This effect will *increase* the mass transfer rate.

The same two effects are also active for the heat transfer. The similarity between heat and mass transfer can be seen by considering the expressions for the transfer coefficients of mass

$$\kappa = \frac{\mathrm{Sh}D}{d_p} \tag{1.1}$$

and heat

$$\kappa_{\rm th} = \frac{{\rm Nu}D_{\rm th}}{d_p},\tag{1.2}$$

where d_p is the particle diameter, Sh and Nu are the Sherwood and Nusselt numbers and D and D_{th} are the mass and thermal diffusivities. For single spherical particles in flows with low and medium particle Reynolds numbers, where the particle Reynolds number Re_p is given by Eq. (2.11), the Sherwood and Nusselt numbers can be approximated by the empirical expressions of Ranz & Marshall (1952)

$$Sh = 2 + 0.69 Re_p^{1/2} Sc^{1/3}$$
(1.3)

$$Nu = 2 + 0.69 Re_p^{1/2} \Pr^{1/3},$$

where

$$Sc = \nu/D \tag{1.4}$$

is the Schmidt number and

$$\Pr = \nu/\alpha \tag{1.5}$$

is the Prandtl number, while ν is the viscosity and D and α are the mass and thermal diffusivities, respectively.

A well known example where reacting particles are consumed in a turbulent fluid is the case of pulverized coal combustion, where turbulence influences the process in several ways that are understood to varying degrees. The combustion of coal can be divided into four separate processes; 1) drying, 2) devolatilization, 3) combustion of volatiles and 4) burnout of the remaining char. Processes 1 and 2 involve the evaporation of fluids and thermal cracking of hydrocarbons, while process 3 involves homogeneous reactions. In process 4, gas phase species diffuse to the particle surface and react with the solid carbon. This happens via adsorption of e.g. an oxygen radical to a carbon site on the particle surface and a subsequent desorption of carbon monoxide into the gas phase. This makes process 4 dominated by heterogeneous chemical reactions. Many published studies utilize RANS based simulation tools that describe simulations of pulverized coal conversion in the form of combustion or gasification with an Eulerian-Eulerian approach (Gao et al. (2004) and Zhang et al. (2005)) or a Lagrangian-Eulerian approach (Silaen & Wang (2010);

The effect of turbulence on mass transfer rates of small inertial particles with surface reaction

Vascellari et al. (2014, 2015); Klimanek et al. (2015); Chen et al. (2012, 2000)). However, none of these papers take the effect of turbulence on the heterogeneous char reactions into account. To the knowledge of the authors, the only studies where account is made for this effect are the papers of Luo et al. (2012); Brosh & Chakraborty (2014); Brosh et al. (2015) and Hara et al. (2015) where the Direct Numerical Simulations (DNS) approach is used. In a DNS, all turbulence scales are explicitly resolved on the computational grid, such that the effect of turbulence is implicitly accounted for. However, the DNS approach is extremely costly and can therefore only be used for small simulation domains. For simulations of large scale applications, the RANS or LES based simulation tools will therefore be the only applicable tools for the foreseeable future.

In the current paper, the same framework as was developed by Kruger et al. (2017) has been used and extended. The aim of the paper is to identify the effect of turbulence on the mass and heat transfer of solid particles, and to develop models that describe this effect for all Damköhler numbers. Here, the Damköhler number is defined as the ratio between the integral time scale of the turbulence and the characteristic time scale of the chemical reactions.

2. Mathematical model and implementation

In the current work, the so called point-particle direct numerical simulation (PP-DNS) approach is used. Here, the turbulent fluid itself is solved with the direct numerical simulation (DNS) methodology, where all turbulent scales are resolved and no modelling is needed. The particles are however not resolved, but rather treated as point particles where the fluid-particle momentum, mass and heat interactions are modelled. The point particle approach is a simplification that relies heavily on the quality of the models. The alternative approach, which is to resolve the particles and their boundary layer, is extremely CPU intensive and can currently not be done for more than a few hundred particles, even on the largest computers (Deen & Kuipers (2014)).

In this work we use THE PENCIL-CODE (2009), which is a high-order finite-difference code for compressible hydrodynamic flows on a Cartesian mesh. It is highly modular and can easily be adapted to different types of problems. The code runs efficiently under MPI on massively parallel shared- or distributed-memory computers, like e.g. large Beowulf clusters. In THE PENCIL CODE, the fluid flow is described by the Eulerian formalism, while the Lagrangian formalism is used for the particle transport. Using the Eulerian formalism for the fluid flow is a valid approximation as long as the fluid can be assumed to be a continuum and as long as the diameter of each Lagrangian particle is not much smaller than the mean free path of a typical fluid molecule.

A number of simplifications are made in this paper. This has been done in order to make the simulations less CPU intensive, and, even more importantly, to isolate the dominating physical mechanisms. The particles are considered to be ever lasting, i.e. they are not consumed. This has been done in order to get more accurate statistics for the model development, but has no effect on the results as such. The results obtained with everlasting particles are equally valid also for particles with variable radii. The reaction on the particle surface converts reactant A to product B;

$$A \to B$$
 (2.1)

isothermaly, i.e.; there is no production or consumption of heat, such that only the mass transfer effect is considered. As explained in the introduction, the effect on the heat transfer rate will be similar to the effect on the mass transfer rate. As reactant A is converted to product B, the thermodynamical and transport properties are not changed. The fact that the reactions are isothermal, and that the products do not influence the thermodynamical nor transport properties of the gas phase in our simulations, will obviously have an influence on the results of individual runs, but it will not, however, influence the resulting model that is built in this paper. The model is made generic and independent of these kind of application dependent properties. The reason for this

is that the model, which will be used in RANS simulations of some application with particles that experience surface reactions at their solid surface, will always use the real instantaneous temperature and composition field from the RANS simulation. Furthermore, the reactions are assumed to be diffusion controlled, i.e.; the chemical kinetics are infinitely fast. This has been done in order to identify the interesting effects. Note that the effects we are considering here are only affecting the transfer rates to the particles, not the chemical kinetics. This means that if the reactions were kinetics controlled, there would be no effect of the turbulence. Finally, particle collisions are ignored since, even in the densest clusters, the volume fraction of the particles is relatively small. Additionally, since particles that do collide will typically continue to stay within the cluster, allowing for particles to collide will not have an effect on the results as long as they do not agglomerate.

2.1. Fluid equations

The equations determining the motion of the carrier fluid are given by the continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{u}) = 0, \qquad (2.2)$$

and the Navier-Stokes equation

$$\rho \frac{\mathrm{D}u}{\mathrm{D}t} = -\nabla P + \nabla \cdot (2\mu S) + \rho f + F.$$
(2.3)

Here, ρ , u, $\mu = \rho v$ and v are the density, velocity and dynamic and kinematic viscosities of the carrier fluid, respectively. The pressure *P* and the density ρ are related by the isothermal sound speed c_s , i.e.,

$$P = c_s^2 \rho, \tag{2.4}$$

while the trace-less rate of strain tensor is given by

$$\boldsymbol{S} = \frac{1}{2} \left(\boldsymbol{\nabla} \boldsymbol{u} + (\boldsymbol{\nabla} \boldsymbol{u})^T \right) - \frac{1}{3} \boldsymbol{\nabla} \cdot \boldsymbol{u}.$$
(2.5)

Kinetic energy is injected into the simulation box through the forcing function f, which is solenoidal and non-helical and injects energy and momentum perpendicular to a random wave vector whose direction changes every time-step (Haugen et al. 2012; Kruger et al. 2017). Similar kinds of forcing has also previously been used for particle laden flows by other groups (Bec et al. 2007). The energy injection rate is maintained at a level such that the maximum Mach number is always below 0.5. The domain is cubic with periodic boundaries in all directions. The momentum exchange term, F, is chosen to conserve momentum between the fluid and the solid particles, i.e.,

$$F = -\frac{1}{V_{\text{cell}}} \sum_{k} m^{k} a^{k}$$
(2.6)

when V_{cell} is the volume of the grid cell of interest and m^k and a^k are the mass and acceleration (due to fluid drag) of the k'th particle within the grid cell.

The equation of motion of the reactant has the well-known advection-reaction-diffusion form:

$$\frac{\partial X}{\partial t} + \boldsymbol{u} \cdot \nabla X = D\nabla^2 X + \tilde{R}, \qquad (2.7)$$

where X, \overline{M}_c and D are the mole fraction, the mean molar mass and the diffusivity of the reactant, respectively. The last term in Eq. (2.7), \tilde{R} , is the sink term due to the gas-solid reactions on the surface of the solid particles.

The effect of turbulence on mass transfer rates of small inertial particles with surface reaction \$

2.2. Particle equations

The N_p particles that are embedded in the flow are treated as point particles, which means that they are assumed to be significantly smaller than the viscous scale of the fluid and the diffusive scale of the reactant. The motion of the k'th particle is described by the equations for position

$$\frac{d\boldsymbol{r}^{k}}{dt} = \boldsymbol{V}^{k} \tag{2.8}$$

and velocity

$$\frac{dV^k}{dt} = a^k \tag{2.9}$$

when the particle acceleration due to fluid drag is given by $a^k = \left[u(r^k) - V^k\right]/\tau^k$. Note that gravity is neglected in this work. The particle response time is given by (Schiller & Naumann (1933))

$$\tau^k = \frac{\tau_{\rm St}}{1 + f_c^k} \tag{2.10}$$

when $\tau_{\text{St}} = S d_p^2 / 18\nu$ is the Stokes time, $f_c^k = 0.15 (\text{Re}_p^k)^{0.687}$ is a Reynolds number correction term to the classical Stokes time, $S = \rho_p / \rho$ is the density ratio, ρ_p is the material density of the particles,

$$\operatorname{Re}_{p}^{k} = \frac{|\boldsymbol{u}(\boldsymbol{r}^{k}) - \boldsymbol{V}^{k}|d_{p}}{\nu} = \frac{u_{\operatorname{rel}}^{k}d_{p}}{\nu}$$
(2.11)

is the particle Reynolds number of particle k and d_p is the particle diameter.

2.3. Surface reactions

Let us now model the reactive term. We assume that the reactions are limited to the surface of the particles and that the reactions are diffusion controlled, i.e. that all reactant that reaches the particle surface is consumed immediately[†]. The reactive term can then be written as

$$\tilde{R} = \frac{1}{V_{\text{cell}}} \sum_{k} A_{p}^{k} \kappa X_{\infty}^{k}$$
(2.12)

where $A_p = \pi d_p^2$ is the external surface area of the particle, the mass transfer coefficient is given by Eq. (1.1) and Sh is the Sherwood number.

To couple the reactive particle with the continuum equations we use the following prescription; for the k-th particle, which is at position r^k , we set

$$X_{\infty}^{k} = X(\boldsymbol{r}^{k}), \qquad (2.13)$$

i.e.; the far field reactant mole fraction is set equal to the reactant mole fraction of the fluid cell where the particle is. In the current work, the particle Sherwood number is determined by the expression of Ranz & Marshall (1952) (see Eq. (1.3) in the introduction), which is in contrast to the work of Kruger et al. (2017) where the Sherwood number was set to a constant value of 2, which corresponds to the Sherwood number in a quiescent flow (see Eq. (1.3)).

2.4. The reactant consumption rate

It is useful to define a reactant consumption rate as

$$\alpha = -\overline{\left(\frac{\tilde{R}}{X_{\infty}}\right)} = n_p \overline{A_p \kappa}, \qquad (2.14)$$

† It is possible to relax the assumption of diffusion controlled reactions by also accounting for chemical kinetics at the particle surface, see Kruger et al. (2017).

when \overline{O} represents the volume average of flow property O and n_p is the particle number density. If everything is assumed to be homogeneously distributed over the volume, the reactant consumption rate is given by

$$\alpha_{\rm hom} = n_p A_p \overline{\kappa} = n_p A_p \frac{\overline{\rm Sh}D}{d_p}$$
(2.15)

for a given diffusivity, particle size and number density. The mass transfer coefficient and Sherwood number averaged over all particles are given by $\overline{\kappa}$ and \overline{Sh} , respectively. The averaging should be made over the scale of the unresolved turbulent eddies.

In many RANS based simulation tools, where the local fluid velocity is not resolved, it is common to neglect the relative velocity difference between the turbulent eddies and the particles. From Eq. (1.3) it is clear that neglecting the relative velocity, which means that $\text{Re}_p = 0$, yields that Sh = 2. Since the effect of particle clustering is also neglected in such models, the modelled reactant consumption rate becomes;

$$\alpha_{\text{Sh,Da}} = \lim_{\text{Sh}\to 2,\text{Da}\to 0} \alpha = n_p A_p \frac{2D}{d_p}.$$
(2.16)

In the following, $\alpha_{Sh,Da}$ will be used for normalization, such that the normalized decay rate is given

$$\tilde{\alpha} = \frac{\alpha}{\alpha_{\rm Sh,Da}}.$$
(2.17)

It is useful to define the Damköhler number, which is the ratio of the typical turbulent and chemical time scales, as

$$Da = \frac{\tau_L}{\tau_c} \tag{2.18}$$

where $\tau_L = L/u_{\text{rms}}$ is the integral time scale of the turbulence, L is the turbulent forcing scale, u_{rms} is the root-mean-square turbulent velocity and the chemical time scale is

$$\tau_c = 1/\alpha_{\rm Sh,Da}.\tag{2.19}$$

Particles in a turbulent flow field will tend to form clusters with higher particle number density than the average (Squires & Eaton 1991; Eaton & Fessler 1994; Toschi & Bodenschatz 2009; Wood et al. 2005). If the chemical time scale is short compared to the life-time of the clusters, the reactant concentration within the clusters will be much lower than outside the clusters. On the other hand, if the particle number density is low, the particle clusters will not have enough time to consume a significant fraction of the reactant during the life-time of the clusters. By assuming that the life-time of the clusters is of the order of the turbulent time scale, it is clear that the reactant concentration of particle flows with low Damköhler number will behave as if the particles were homogeneously distributed over the volume, i.e.; for small Damköhler numbers there is no effect of particle clustering on the reactant consumption.

From Eqs. (2.15) - (2.19) it can be deduced that for the homogeneous case, and then also for all cases with low Damköhler numbers, the reactant consumption rate will scale linearly with the Damköhler number for a given turbulent flow field, such that

$$\alpha_{\rm hom} = \frac{{\rm Da}\,\overline{\rm Sh}}{\tau_L}\,\,(2.20)$$

When relaxing the restriction to small Damköhler numbers, the effect of particle clustering eventually comes into play. Kruger et al. (2017) have shown that the reactant consumption rate

The effect of turbulence on mass transfer rates of small inertial particles with surface reactions

is given by

$$\alpha = \frac{\alpha_c \alpha_{\rm hom}}{\alpha_c + \alpha_{\rm hom}} \tag{2.21}$$

when α_c is a cluster dependent decay rate. (Note that since Kruger et al. assumed the Sherwood number to be 2, their α_{hom} equals our $\alpha_{\text{Sh,Da}} = \text{Da}/\tau_L$.) From this expression, the following normalized reactant consumption rate is found to be

$$\tilde{\alpha} = \frac{\alpha}{\alpha_{\rm Sh,Da}} = \frac{\alpha_c \tau_L}{\alpha_c \tau_L + \text{Da}\overline{\text{Sh}}/2} \frac{\overline{\text{Sh}}}{2},$$
(2.22)

when Sh is given by Eq. (1.3) and the corresponding relative velocity between the particle and the fluid is determined by a model (which will be obtained in the next subsection). For diffusion controlled reactions, the modified reactant decay rate, as given by Eq. (2.22), is a measure of the relative modification to the mass transfer rate due to the effect of turbulence. This means that a modified Sherwood number can now be defined that accounts for the effect of turbulence;

$$\operatorname{Sh}_{\mathrm{mod}} = 2\tilde{\alpha} = \overline{\operatorname{Sh}} \, \frac{\alpha_c \tau_L}{\alpha_c \tau_L + \mathrm{Da}\overline{\mathrm{Sh}}/2}.$$
 (2.23)

In the limit of small Damköhler numbers, this expression reduces to $Sh_{mod} = \overline{Sh}$, as expected.

By employing the modified Sherwood number given by Eq. (2.23), one can now use the common expression for the reactant consumption rate, as given by Eq. (2.15), to find the real reactant consumption rate. In most cases, however, one needs the particle conversion rate \dot{n}_{reac} for individual particles, which is closely connected to the reactant decay rate. For diffusion controlled reactions, the particle conversion rate is given by $\dot{n}_{reac} = -\bar{\kappa}X_{\infty}C_g$, where C_g is the molar concentration of the gas phase. The mass transfer coefficient is now obtained by using the modified Sherwood number in Eq. (1.1), such that

$$\overline{\kappa} = \frac{D\mathrm{Sh}_{\mathrm{mod}}}{d_p}.$$
(2.24)

In many applications, the reaction rate is not purely diffusion controlled. This can be accounted for by including the effect of reaction kinetics at the particle surface. The corresponding particle conversion rate can then be expressed as (Kruger et al. 2017)

$$\dot{n}_{\rm reac} = -\frac{\lambda \overline{\kappa}}{\lambda + \overline{\kappa}} X_{\infty} C_g, \qquad (2.25)$$

where λ is the surface specific molar conversion rate. Since the reaction kinetics is only dependent on the conditions at the particle surface, the surface specific molar conversion rate is not affected by the turbulence. This is, as we have already seen, not the case for the mass transfer coefficient, which is now given by Eq. (2.24).

The main conclusion of this paper is that particles with surface reactions must account for the effect of turbulence on the mass transport to the particles. This is done by using the modified Sherwood number, as defined in Eq. (2.23). In this way, all the common machinery for calculating particle reaction rates can still be used since the effects of the turbulence are incorporated into the modified Sherwood number.

3. Results

In all of the following, statistically stationary homogeneous and isotropic turbulence is considered. The Reynolds number is varied by changing the domain size while maintaining constant viscosity and turbulence intensity. The Damköhler number is varied by changing the number of particles, while keeping everything else the same. For the simulations in this work, up to TABLE 1. Summary of the different groups of simulations. For every row in the table, a range of simulations with different Damköhler numbers have been performed. This means that each row in the table corresponds to a given line in figures 5 and 6, while individual points in the same figures corresponds to individual simulations. The fluid density is unity while the Schmidt number is 0.2 and the viscosity is 2×10^{-4} m²/s for all simulations. The Taylor micro-scale Reynolds number is given by Re_{λ} = $u'^2 [15/v\epsilon]^{1/2}$ when $u' = u_{rms}/\sqrt{3}$. Columns 2-5 list input parameters, while the last six columns give output from the simulations. The averaged Sherwood number for all particles is given by Sh. The cluster decay rate, which is defined in Eq. (3.15), is given by α_c .

 12.8×10^6 particles have been used. The accuracy of the simulations have been assessed by performing grid independence studies to verify that the turbulence is properly resolved. In addition, the number of particles has been increased to check that the results are independent of this parameter. When increasing the number of particles, the size and material density of the particles had to be augmented in order to maintain constant Damköhler and Stokes numbers. All relevant simulations are listed in table 1.

3.1. The mean relative particle velocity

In order to predict a representative value of the particle Sherwood number from Eq. (1.3), the particle Reynolds number Re_p is required. From Eq. (2.11) it is clear that this also requires the relative particle velocity u_{rel} , which will be found in this subsection.

Given a particle with a response time that equals the Stokes time;

$$\tau_p = \frac{S d_p^2}{18\nu},\tag{3.1}$$

such that $\tau_k < \tau_p < \tau_L$, where τ_k is the Kolmogorov time scale and τ_L is the integral time scale. With respect to the particle-turbulence interactions, the turbulent power spectrum may be divided into three distinct regimes, based on the relation between the particle response time and the turbulent eddy turnover time τ_{eddy} . The first regime is defined as the section of the turbulent power spectrum where the turbulent eddies have turnover times that are much larger than the

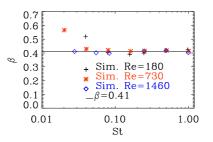

FIGURE 1. The parameter β , relating the relative particle velocity to the sub-scale velocity as defined in Eq. (3.9), is shown for a number of different DNS simulations as a function of Stokes number.

response time of the particles, i.e. where $\tau_{eddy} \gg \tau_p$. All the turbulent eddies in this regime will see the particles as passive tracers, which follow the fluid perfectly. i.e., there will be no relative velocity between the particles and the eddies. The third regime is defined as the part of the power spectrum where the turbulent eddies have much shorter time scales than the particles, i.e. where $\tau_{eddy} \ll \tau_p$. The eddies in regime three will see the particles as "heavy bullets" that move in straight lines, without being affected by the motion of the eddies. Hence, the velocity of these eddies will contribute to the relative particle-fluid velocity. The second regime is now defined as the relatively thin band in-between regimes one and three, where $\tau_{eddy} \approx \tau_p$. These are the eddies that are responsible for particle clustering, since they are able to accelerate the particles to a level where they are thrown out of the eddy due to their inertia. In the following, we will refer to a typical eddy in regime two as a *resonant eddy*, and we define the scale of this eddy as ℓ . The resonant eddies are identified by their time scale, τ_ℓ , which is of the order of the particle response time, τ_p . For convenience, we set the two time scales equal, such that

$$\tau_{\ell} = \tau_p. \tag{3.2}$$

Based on the definitions above, it is clear that the largest turbulent eddies that yield a relative velocity between the fluid and the particles, are the resonant eddies. By assuming Kolmogorov scaling, the velocity of the resonant eddies is known to be $u_{\ell} = u_{\rm rms} (\ell/L)^{1/3}$, which can be combined with the above expression for the time scales to yield

$$k_{\ell} = k_L \mathrm{St}^{-3/2} \tag{3.3}$$

when the particle Stokes number is defined as

$$St = \frac{\tau_p}{\tau_L} \tag{3.4}$$

and $k_{\ell} = 2\pi/\ell$ and $k_L = 2\pi/L$ are the wave-numbers of the resonant eddies and the integral scale, respectively. In obtaining Eq. (3.3), it has also been used that the turnover time of the resonant eddies is $\tau_{\ell} = \ell/u_{\ell}$, while that of the integral scale eddies is $\tau_{L} = L/u_{\rm rms}$.

Since all scales smaller than ℓ will induce a relative velocity between the particles and the fluid, it is reasonable to assume that the mean relative velocity between the fluid and the particles will be a certain fraction β of the integrated turbulent velocity \tilde{u}_{ℓ} of all scales smaller than ℓ , such that

$$u_{\rm rel} = \beta \tilde{u}_{\ell} \tag{3.5}$$

when \tilde{u}_{ℓ} is defined as

$$\frac{1}{2}\tilde{u}_{\ell}^2 = \int_{k_{\ell}}^{k_{\eta}} E(k)dk \tag{3.6}$$

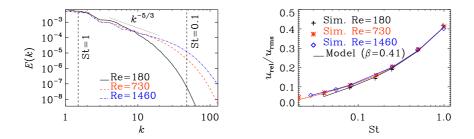

FIGURE 2. Left panel: kinetic energy spectrum for DNS simulations with different Reynolds numbers. Right panel: relative particle velocity as a function of Stokes number. In the right panel, symbols represent simulation results, while lines correspond to the model given by Eq. (3.9) when the value of β has been chosen to be 0.41.

and $k_{\eta} = 2\pi/\eta$ is the wave-number of the Kolmogorov scale ($\eta = (\nu^3/\epsilon)^{1/4}$), where ϵ is the dissipation rate of turbulent kinetic energy. Integration of Eq. (3.6) yields

$$\tilde{u}_{\ell} = u_{\rm rms} \sqrt{\frac{k_{\ell}^{-2/3} - k_{\eta}^{-2/3}}{k_{L}^{-2/3} - k_{\eta}^{-2/3}}}$$
(3.7)

for $E(k) = c\epsilon^{2/3}k^{-5/3}$ when it has been used that the total turbulent kinetic energy is given by

$$\frac{1}{2}u_{\rm rms}^2 = \int_{k_1}^{k_\eta} E(k)dk,$$
(3.8)

where k_1 is the wave-number of the largest scale in the simulation. Combining Eqs. (3.3) and (3.7) with Eq. (3.5) finally yields

$$u_{\rm rel} = \beta u_{\rm rms} \sqrt{\frac{{\rm St}k_L^{-2/3} - k_\eta^{-2/3}}{k_L^{-2/3} - k_\eta^{-2/3}}}.$$
(3.9)

The unknown constant in this equation, β , can be determined numerically from Eq. (3.5), i.e. $\beta = u_{rel}/\tilde{u}_{\ell}$. Here, the mean relative particle velocity u_{rel} is found directly from DNS simulations, while \tilde{u}_{ℓ} is calculated from Eq. (3.7). It is seen from figure 1 that β is close to 0.41 for most Stokes and Reynolds numbers. The main exception is for low Reynolds and Stokes numbers, where β is significantly larger. This can be understood by inspecting the left panel of figure 2, where it is seen that for Re = 180 and St < 0.1, we are already far into the dissipative sub-range, where our model is not expected to be correct since it relies on a Kolmogorov scaling.

It is surprising to see that Eq. (3.9) reproduces the relative particle velocity for such low Stokes numbers, even for the smaller Reynolds numbers. This may be explained by reconsidering Eq. (3.2), where we assumed that the resonant eddies correspond to the eddies that have *exactly* the same turnover time as the response time of the particles. This is just an order of magnitude estimate, and a more correct expression would probably be

$$\tau_{\ell} = \gamma \tau_p, \tag{3.10}$$

where γ is of the order of unity. More work should, however, be devoted to understanding the coupling between the particles and the turbulent eddies. In particular, a more exact definition of the resonant eddies is needed. We nevertheless believe that β is a universal property of the HIP approximation and the Navier-Stokes equations that will have a constant value for all Re and St as long as the resonant eddies are within the inertial range.

In the right panel of figure 2, the average relative particle velocity, as found from the DNS

simulations (symbols), is compared with the predicted values from Eq. (3.9) (solid lines). It is seen that the fit is rather good for most Reynolds and Stokes numbers. This supports the use of Eq. (3.9) for predicting the relative particle velocity.

3.2. The cluster size

The typical size of the clusters ℓ is assumed to be the size of the resonant eddies. From Eq. (3.3) this yields a cluster size of

$$\ell = L \mathrm{St}^{3/2}.\tag{3.11}$$

It can be seen from figure 3 that the distribution of the particle number density, which is defined as the number of particles per unit volume, does indeed show more small scale variation for the smaller Stokes numbers. This has been quantified in figure 4 where the power spectrum of the particle number density is shown. Here we see that the spectrum peaks at large scales for St = 1 while the peak is located at much smaller scales for smaller Stokes numbers. The peak in the spectrum does not, however, follow Eq. (3.11) as accurately as expected. The reason for this is most likely that power spectra are not the right diagnostics to study the size of particle clusters. Alternatively, the constant in the definition of the resonant eddies may not be unity (see e.g. Eq. (3.10)). Another possible reason for the discrepancy may be finite Reynolds number effects, which means that the clustering eddies are outside, or close to being outside, the inertial range. Since Eq. (3.11) is based on Kolmogorov statistics, this would give simulation-results that violate Eq. (3.11). Finally, even poor statistics due to too few particles relative to the number of clustering eddies, which means that the clusters are not populated with enough particles, may also yield results that do not follow Eq. (3.11). This can be understood by assuming a case with only two particles and a thousand clustering eddies. By visualizing a snapshot of the particle positions, it would not be possible to identify any particle cluster, because the two particles would seem to be randomly distributed. If, on the other hand, there were a thousand particles and only two turbulent eddies, it would be straight forward to see that the particles tend to cluster outside the eddies.

The power spectrum P can be integrated to yield a measure of the strength in the particle number density fluctuations, given by the root-mean-square (rms) particle number density;

$$n_{\rm rms} = \int P dk. \tag{3.12}$$

It is found that the rms particle number density is decreasing with Stokes number. More specifically, $n_{\rm rms}$ is 1.6, 1.5, 1.2 and 0.8 for Stokes numbers of 1, 0.3, 0.1 and 0.03, respectively. This means that the high density regimes have higher particle number densities for larger Stokes numbers.

3.3. Reactant consumption rate

The normalized reactant consumption rate is shown in figure 5. The symbols correspond to the results from the DNS simulations, as given by Eq. (2.17), where α is found from Eq. (2.14), while the solid lines are given by Eq. (2.22). Here, the Stokes number is found by using the model for the relative velocity, as given by Eq. (3.9), in the expression for the Sherwood number (Eq. (1.3)). The value of the cluster decay rate, α_c , is the only free parameter and it is chosen by a best fit approach between the DNS results (Eq. (2.14)) and the model results (Eq. (2.21)) for α . The values of α_c are found in table 1.

The value of $\tilde{\alpha}$ for small Damköhler numbers equals the Sherwood number divided by two, while the Damköhler number for which $\tilde{\alpha}$ starts to decrease is determined by the cluster decay rate α_c . Overall, the model seems to follow the results from the DNS simulations rather well.

From figure 5 it can be seen that for large Stokes numbers, the curves for the normalized decay rates of a given Stokes number overlap for different Reynolds numbers if the Reynolds number

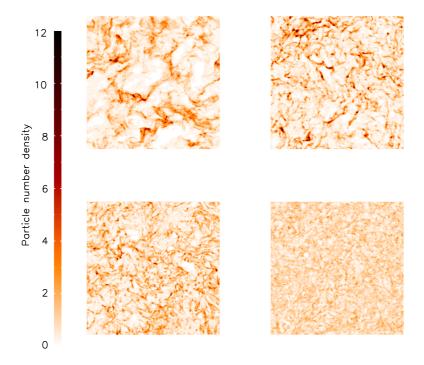

FIGURE 3. Particle number density for St = 1 (upper left), St = 0.3 (upper right), St = 0.1 (lower left) and St = 0.03 (lower right) (runs 3A, 3B, 3C and 3D in table 1). It is only the Stokes number that differs between the four simulations, all other parameters, including the total number of particles, are the same.

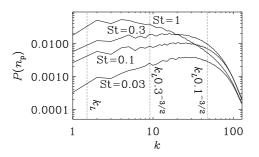

FIGURE 4. Power spectrum of particle number density for runs 3A, 3B, 3C and 3D in table 1.

is high enough. This is because the resonant eddies are at scales larger than the dissipative subrange. So increasing the Reynolds number, which may be considered a shift of the dissipative sub-range to smaller scales, is not affecting the resonant eddies, and hence also the clustering is unaffected. If, however, the Reynolds or the Stokes number is small, such that the resonant eddies are in the dissipative sub-range, a change in Reynolds number will have an effect on the normalized decay rate ($\tilde{\alpha}$). The line labeled "Kruger" represents the results presented in Kruger et al. (2017), where Re = 250 and the Sherwood number was set to 2, while the Stokes number was unity. Except from a downwards shift, the results from Kruger et al. (2017) follow the same trends as obtained with Sh > 2. The reason for the downward shift can be seen from Eq. (2.22),

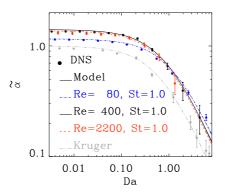

FIGURE 5. Normalized decay rate as a function of Damköhler number for Stokes number of unity (runs 1A-3A). Symbols represent simulation results, while lines corresponds to the model given by Eq. (2.22). The values of α_c , which are used in Eq. (2.22), can be found from table 1. The line labeled "Kruger" corresponds to the results shown in Kruger et al. (2017), where the Sherwood number was set to 2. The Reynolds number for this case was 250, while the Stokes number was unity.

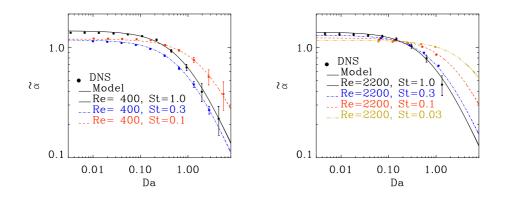

FIGURE 6. Normalized decay rate as a function of Damköhler number for different Stokes numbers. The left panel show the results for Re = 400 (runs 2A-C) while the right panel is for Re = 2200 (runs 3A-3D). Symbols represent simulation results, while lines corresponds to the model given by Eq. (2.22). The values of α_c , which are used in Eq. (2.22), can be found from table 1.

where it is shown that for small Damköhler numbers the value of $\tilde{\alpha}$ scales linearly with the mean Sherwood number, hence, the smaller Sherwood number of Kruger et al. (2017) et al. leads to smaller values of $\tilde{\alpha}$.

Figure 6 shows that by decreasing the Stokes number, the normalized reactant decay rate stays unchanged up to larger Damköhler numbers. This means that the effect of particle clustering is weaker for smaller Stokes numbers. This is expected since the limit of very small clusters corresponds to individual particles, where $\tilde{\alpha}$ is independent of Da.

If the turbulence is unchanged, a reduction in the Stokes number will, as is apparent from Eq. (3.9), yield a reduced relative velocity between the particles and the fluid. Based on Eq. (1.3), it is clear that this results in a decreased Sherwood number as long as the particle diameter is not changed while changing the Stokes number. This effect is identified in the right hand plot of figure 6, where it is observed that the normalized reactant decay rate is monotonically decreasing with the Stokes number for small Damköhler numbers. (Please note that for small Damköhler

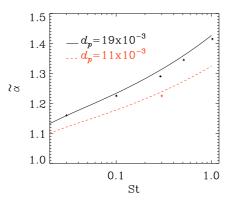

FIGURE 7. Sherwood number as a function of Stokes number for Re = 400 and Da = 0.01. Solid lines correspond to modelled results while symbols represent results from individual simulations.

numbers, the normalized reactant decay rate equals half of the Sherwood number.) The same monotonic decrease is, however, not observed for the cases with Re=400, which is visualized in the left hand plot of figure 6. This is because, as can be seen from table 1, for the Re=400 cases the particle diameter is smaller for St=0.3 than for St=0.1, which happens to yield the same Sherwood number for St=0.1 and St=0.3, and hence, the normalized reactant decay rates for small Damköhler numbers are equal.

Particle size is important, and in the following it is considered by the effects it has on the Sherwood number. From Eq. (2.23), it is clear that

$$\tilde{\alpha} = \overline{\mathrm{Sh}}/2 \tag{3.13}$$

for Da \rightarrow 0. By inserting Eqs. (2.11) and (3.9) into Eq. (1.3), the following expression for the mean particle Sherwood number is obtained;

$$\overline{Sh} = 2 + 0.69 Sc^{1/3} \sqrt{\frac{u_{\rm rms}\beta d_p}{\nu}} \left[\frac{St k_L^{-2/3} - k_\eta^{-2/3}}{k_L^{1/3} - k_\eta^{-2/3}} \right]^{1/4}.$$
(3.14)

By combining the two equation above, one can now plot $\tilde{\alpha}$ as a function of Stokes number for different particle diameters. This is done in figure 7, where the solid lines correspond to the expression discussed above and the symbols represent data from individual simulations with Da = 0.01. One can see from the figure that, except from a small downward shift, the simulation results follow the predictions. The reason for the downward shift is that the Damköhler number for the simulations is not in reality infinitely small, and hence the normalized decay rate is slightly smaller than it would have been for $Da \rightarrow 0$.

3.4. The cluster decay rate

If the chemical time scale is much shorter than the lifetime of the particle clusters, the interior of the clusters will quickly be void of reactants. This means that the reactant consumption rate is controlled by the flux of reactant to the surface of the clusters, where the reactant will be consumed at the exterior of the cluster. Based on this, it is clear that for large Da (small τ_c), the clusters behave as large solid particles, or super-particles. Following Kruger et al. (2017), the reactant decay rate is then given by the so called cluster decay rate;

$$\alpha_c = n_c \overline{\kappa}_c \overline{A}_c \tag{3.15}$$

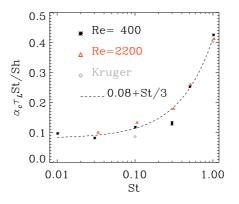

FIGURE 8. The product $\alpha_c \tau_L$ St as a function of St for runs with resonant eddies in the inertial range. Symbols represent simulation results, while the line corresponds to the model given by Eq. (3.18). The point labeled "Kruger" corresponds to results obtained from data found in Kruger et al. (2017), where the Sherwood number was set to 2 and the Reynolds number was 250.

when $n_c = A_1 \ell^{-3}$ is the number density of clusters (or super-particles), $\overline{\kappa}_c = D_t \overline{Sh}/\ell$ is the reactant diffusion rate to the super-particles, $\overline{A_c} = A_2 \ell^2$ is the surface area of the clusters, D_t is the turbulent diffusivity that carries the reactant from the surrounding fluid to the surface of the clusters and A_1 and A_2 are constants that depend on the dimensionality of the clusters. It is clear that turbulent eddies larger than ℓ , as given by Eq. (3.11), can not participate in the turbulent transport of reactants to the clusters, while eddies slightly smaller than ℓ will participate. A first approximation of the turbulent diffusivity to the surface of the clusters is therefore given by

$$D_t = u_\ell \ell = u_L \text{LSt}^2. \tag{3.16}$$

By combining the above, taking into account Eq. (3.11), it is found that

$$\frac{\alpha_c \tau_L \mathrm{St}}{\mathrm{Sh}} = A_1 A_2, \tag{3.17}$$

where the right hand side should be constant for resonant eddies well inside the inertial range. From figure 8, it can be seen that the right hand side of the above equation is constant only for Stokes numbers smaller than ~ 0.3. The values of the variables on the left hand side of Eq. (3.17) are all found in table 1. Since the value of the right hand side starts to increase already for St = 0.3, this may once again indicate that γ from Eq. (3.10) is different from unity. The discrepancy may also be due to the fact that when it comes to the shape of the particle clusters, a large scale strain may stretch them. For St ~ 1, there are no vortices that are larger than the clusters, and hence the dimensionality of the clusters becomes different. This will inevitably yield different values of A_1A_2 . The value of the geometric coefficients can be fitted by

$$A_1 A_2 = 0.08 + \text{St}/3, \tag{3.18}$$

but this is just an empirical fit and more work is required in order to understand the fundamentals behind the shape and size of the particle clusters.

In figure 8, it can be seen that the two points for St = 0.3 and Re = 400 are very close together. Since these two simulations had different particle sizes, the fact that they yield essentially the same value of A_1A_2 supports the assumption that the expression for A_1A_2 , as shown in Eq. (3.18), is independent on particle size.

4. Conclusion

In this work, the effect of turbulence on the mass (and heat) transfer between inertial particles and the embedding fluid is studied. The turbulence is shown to have two effects on the mass transfer. The first effect is active for all Damköhler numbers, and here the turbulence increases the mass transfer rate due to the relative velocity between the particles and the fluid. A corresponding model for the relative velocity between the fluid and the particles is given by Eq. (3.9), which uses basic variables of the flow. This model is the first main result of this paper. With this, adding effects of relative velocity into RANS based simulations is straight forward.

The second effect with which turbulence influences the mass transfer rate is through the clustering of particles. It is shown in § 3.2 and § 3.3 that the size of the particle clusters increases with the particle Stokes number, and that the clustering decreases the overall mass transfer rate between the particles and the fluid. It is also clear that the effect of clustering is strong, and a reduction in reactant decay by a factor of 10 is seen already for Damköhler numbers of the order of 10. This is a confirmation of the findings of Kruger et al. (2017). For many applications, it may therefore lead to critically large errors to neglect the effect turbulent clustering of particles has on the reaction rate. In the current work, a model has been developed that takes this effect into account and incorporates it into a modified Sherwood number. This is done by combining Eq. (2.22) and Eq. (2.23) with Eq. (3.17), such that the modified Sherwood number becomes

$$Sh_{mod} = \overline{Sh} \frac{A_1 A_2}{A_1 A_2 + DaSt/2}$$
(4.1)

when A_1A_2 is given by Eq. (3.18). The above equation should be used, together with e.g. Eqs. (2.24) and (2.25), to obtain the correct mass transfer rate to the particles in standard RANS simulation tools. This is the second main result of this paper.

More work is still required in order to fully understand the size and dimensionality of the the particle clusters. As of now, a unique way of characterizing particle clusters does not exist, and very little work has actually been put into the study of large-scale clustering of particles.

The work presented here is related to mono-disperse particles. Since particles of different Stokes numbers will cluster in different regions of the flow, one may expect that the effect of particle clustering on the reactant decay rate is reduced for very broad particle size distributions. This should be studied in future work.

Acknowledgements

The research leading to these results has received funding from the Polish-Norwegian Research Program operated by the National Centre for Research and Development under the Norwegian Financial Mechanism 2009-2014 in the frame of Project Contract No Pol-Nor/232738/101/2014. The Research project "Gaspro", financed by the research council of Norway (267916), has also contributed to this research.
