Abstract

The semi-hydrogenation of acetylene ($C_2H_2 + H_2 = C_2H_4$, $\Delta H = -172 \text{ kJ mol}^{-1}$) is a well-studied reaction that is important for purification of ethylene, C_2H_4 , feed used in polyethylene production. Pd-based catalysts are most commonly used to remove acetylene from ethylene feed prior to Ziegler-Natta polymerization because acetylene is a poison for Ziegler-Natta catalysts. New applications of the analogous catalytic processes, with similar requirements on the conversion and selectivity, are considered for the storage of H_2 within the context of the H_2 economy. Here, a combination of experimental and theoretical studies was employed to explore the performance of synthesized Pd nanoparticles and the feasibility of using computational modelling for predicting their catalytic properties. Specifically, a model 5%Pd/Al₂O₃ nanocatalyst was successfully synthesized using high-throughput flame spray pyrolysis (FSP) method. As a catalyst for acetylene semi-hydrogenation, the material shows high conversion of 97%, a modest selectivity of 62%, and a turnover frequency of ethylene formation of 5 s^{-1} . The experimental data were further supported by computational modelling of catalytic properties. Results of microkinetic simulations, based on parameters obtained from DFT calculations, over a Pd₃₀/Al₂O₃(100) model system were correlated with experiments. The insights from this direct comparison of theory and experiments provide indications for future improvements of the theoretical predictions and for novel types of materials with improved catalytic properties.

Keywords

Heterogeneous catalysis, Hydrogenation, Kinetics, DFT, Modelling, Nanoclusters.

1. Introduction

An important industrial example of the semi-hydrogenation of acetylene, C_2H_2 , to ethylene, C_2H_4 ($C_2H_2 + H_2 = C_2H_4$), is related to the need to reduce to a few ppm the acetylene concentration in the ethylene feedstock for polyethylene polymerization, which is typically produced from steam cracking of hydrocarbons and contains 0.5–2% of acetylene [1]. Without the catalytic semi-hydrogenation, this minor amount of acetylene negatively affects the polymerization process because acetylene poisons the polymerization Ziegler-Natta catalysts. Furthermore, to keep the process economically viable, the catalyst should not further convert ethylene into ethane, meaning that highly selective semi-hydrogenation of acetylene needs to be achieved [2,3]. Similar needs for improving the selectivity of catalysts [4] also emerges from the recent advances in the H_2 economy, whereby catalytic hydrogenation of unsaturated hydrocarbons, such as cyclohexane, methylcyclohexane, decalin, etc. [5] offers a promising pathway to store/use renewable H_2 .

Pd-based catalysts have been employed in semi-hydrogenation of C_2H_2 to C_2H_4 due to their high activity for acetylene conversion. Unfortunately, these catalysts typically exhibit low selectivity because they subsequently convert C_2H_4 to unwanted C_2H_6 [6–8]. They also present limited stability caused by the accumulation of oligomers, which is mostly attributed to the fact that these catalysts provide active sites that enable side reactions [9–11]. An increase in the selectivity and stability of Pd catalysts has been achieved by, for example, the addition of promoters to the catalysts, or by mixing with other metals and metal oxides [12–17]. Despite the numerous studies addressing the improvement of Pd-based catalysts, it is still not possible to increase their selectivity and stability, a goal that requires understanding the catalytic reaction mechanism.

For instance, the reaction pathways of acetylene hydrogenation on Pd(111) surface have been investigated using first-principles DFT calculations, and the results revealed that the hydrogenation of acetylene to vinyl and vinyl to ethylene had similar activation barriers [18]. Later, using first-principles-based kinetic Monte Carlo simulations, Me *et al.* reported that the simulated apparent activation energy, ethylene selectivity and reaction orders were comparable with experiments [19]. More recently, semi-hydrogenation of acetylene over Pd-doped Cu(111) surfaces at low-temperature has been examined by DFT combined with microkinetic modeling [20]. It was found that the ethylene selectivity on a single-Pd-doped Cu(111) surface was higher than that of a monolayer-Pd-doped Cu(111), but the acetylene conversion exhibited inverse behaviors on these two surfaces. Until now, most theoretical studies have focused on the hydrogenation of acetylene over metal surfaces, while the investigations of Pd anchored on a supporting material remain a big challenge [21,22]. Accordingly, to develop advanced catalysts

for semi-hydrogenation of C_2H_2 , it is necessary to achieve a basic understanding of the catalytic reactions on model systems.

Herein, we report new synthesis, characterization, and catalytic hydrogenation properties of a Pd nanocatalyst supported on alumina, Pd/Al_2O_3 . Moreover, we investigate whether a state-of-the-art theoretical modeling can predict the catalytic behavior. The results of this study show a good agreement between the performed experiments and theoretical simulations, which opens a practical opportunity for computational screening of complex catalysts.

2. Experimental

2.1 Catalyst preparation

The flame spray pyrolysis (FSP) sample was produced employing a commercial FSP system (NPS10, Tethis, Italy). The NPS10 is a bench top system that allows the production of FSP nanopowder with laboratory mass-scale for R&D purposes. The burner where the pyrolysis reactions take place is described, for example, by Madler *et al* [23]. In our work, a liquid solution containing the metal organometallic precursors was injected, by a syringe pump (at a rate of $5\text{ cm}^3\text{ min}^{-1}$) through a stainless-steel capillary, into a nozzle where it was dispersed by an oxygen flow of $5\text{ dm}^3\text{ min}^{-1}$ (at a pressure drop of 1.5 bar). A concentric flamelet ring was fed with a premixed mixture of methane/oxygen ($CH_4\ 1.5\text{ dm}^3\text{ min}^{-1}$, $O_2\ 3.2\text{ dm}^3\text{ min}^{-1}$) for generating the supporting flame. Additional oxygen ($5\text{ dm}^3\text{ min}^{-1}$) was supplied by an outer sheath flow to assure enough oxidant for complete conversion of the reactants. The powder was collected on a glassfiber filter (GF/A Whatman, Kent, United Kingdom), 150 mm in diameter. The filter was placed in a water-cooled holder 400 mm above the nozzle.

The liquid precursor was prepared by dissolving Pd(II)-acetylacetonate (99% Strem Chemicals) into acetonitrile (anhydrous, 99.8%, Sigma Aldrich) and then placing a suitable quantity of the obtained solution into a premixed solution of Al(III)-*sec*-butoxide (98%, Strem Chemicals) and Xylene (Carlo Erba) in order to form a final solution of 0.69 M of Al. This synthesized sample will be referred to as **Pd/Al_2O_3 as-synthesized**. The obtained Pd loading was 5%, matching the loading of the reference commercial catalyst, which has been previously comprehensively characterized [11,24].

2.2 Catalyst Characterization

2.2.1 X-ray diffraction. Powder X-ray diffraction (XRD) patterns of the samples were obtained using a X'Pert PRO diffractometer (PANalytical) with a PIXcel 3D detector, set at 45 kV and 40 mA. The sample was grounded to a fine powder and placed in the sample holder. A Bragg Brentano configuration was used in a 2θ range from 20° to 80° with step size of 0.01° and a time

per step of 300 s. Obtained data were analysed with High Score software (PanAnalytical), matching the patterns to International Centre for Diffraction Data (ICDD) database.

2.2.2 Electron microscopy. A probe-corrected FEI Titan 80–200 Chemi-STEM microscope, equipped with a high-brightness Schottky field emission electron gun, was operated at 200 kV to carry out the structural and morphological analysis of the as-synthesized catalyst. The scanning transmission electron microscope (STEM) images were collected by a high-angle annular-dark-field (HAADF) detector in an angle range between 70 mrad and 200 mrad.

2.2.3 X-ray photoelectron spectroscopy. Supported-catalyst powders were analysed in an ESCALAB 250 Xi system (Thermo Scientific). As-synthesized, oxidized, and reduced samples were scraped onto Al foil substrates and measured using a non-monochromatic Al K α X-ray source (operating at 400 W power) to minimize charging artefacts. Peak fitting was performed in Avantage instrument software (Thermo Scientific), choosing a minimal number of components that produced random residuals consistently for all the samples. A convolution of Gaussian and Lorentzian line shapes was used for most of the spectral components; Pd 3d peaks required small asymmetric tails.

The binding energy (BE) scale is based on a BE shift (uniformly applied for all the samples) that placed the aliphatic C 1s peak associated with the supported-catalyst material to 285.0 \pm 0.2 eV, the value chosen based on previous measurements on non-metallic surfaces: polymer films [25], adventitious carbon [26], and alkane chains in self-assembled monolayers [27]. This BE correction places the (unresolved) Al 2p peak associated with the alumina of the catalyst support particles at 74.6 \pm 0.2 eV.

Due to the apparent differential charging, there was a consistent (for all the samples) shift of 2.5 \pm 0.1 eV between the high-resolution elemental peaks corresponding to the supported-catalyst particles and Al-foil substrate: aliphatic C 1s component as well as aluminum-oxide Al 2p and O 1s components. This differential charging shift enabled an unambiguous selection of the aliphatic C 1s component associated with the supported-catalyst particles to be used as the above-mentioned BE reference.

2.2.4 Nitrogen physisorption. The surface area, pore size, and pore volume of the samples were calculated with the determination of the N₂ adsorption-desorption isotherms of the samples at –77 K. The characterization was performed using a Quantachrome Autosorb IQ2 multi-station apparatus. Approximately 100 mg of sample was placed in the sample holder and outgassed under vacuum at 423 K for 240 min before the analysis. The specific surface area of the samples was determined according to the Brunauer–Emmett–Teller (BET) method in the range of (0.05 < P/P₀ < 0.3), the pore size was determined by the Barrett–Joyner–Halenda (BJH) method and

the pore volume was determined using the amount of vapor adsorbed at relative pressure close to unity ($P/P_0 = 0.97$).

2.2.5 Hydrogen Chemisorption. H₂ chemisorption experiments on the Pd catalysts were performed on an AMI-200 Catalyst Characterization apparatus (Altamira) and using the pulsed method, in which pulses of 58 μL of H₂ are injected in the carrier gas (Ar, 25 $\text{cm}^3 \text{min}^{-1}$) that flows through the sample, until the metal saturation, i.e., until the peak area becomes constant. The adsorbed hydrogen quantity is calculated by the integration of each peak that comes from each pulse, determined using a thermal conductivity detector (TCD). Before the analysis, the sample was preheated to 473 K in a pure Ar flow and left for 1 h, next, the flow is exchanged to a pure flow of hydrogen and the sample is reduced for 1 h. After the reduction, the system was purged with Argon and cooled down to 308 K. The hydrogen adsorption stoichiometry was assumed to be 0.5 H₂:Pd [28].

2.3 Catalytic measurements on acetylene semi-hydrogenation reaction

Catalytic measurements were performed in a continuous-flow fixed-bed quartz reactor with internal diameter of 7 mm, using quartz wool to trap the catalyst inside the reactor. The temperature in the bed was measured using a Type K thermocouple connected to a thermocouple data logger, and the gases, acetylene (2.6), hydrogen (5.0) and helium (5.0), were supplied using Bronkhorst mass flow controllers. The reaction products were analysed by a GC-2010 Plus from Shimadzu, equipped with a VP-Alumina column and a flame ionization detector (FID). The reactor was loaded with 1 mg of catalyst diluted in 100 mg silicon carbide (SiC) (60–80 mesh) and prior to each experiment, the catalyst was reduced *in situ* at 473 K for 30 min, under a 20 $\text{cm}^3 \text{min}^{-1}$ H₂ flow.

The conversion and selectivity of the catalysts were evaluated by isothermal and temperature-programmed experiments at atmospheric pressure for both the prepared sample after reduction (**Pd/Al₂O₃ reduced**) and a commercial 5%Pd/Al₂O₃ catalyst (**Pd/Al₂O₃_Ref reduced**) (Alfa Aesar), which was used as reference. In the case of the isothermal experiments at 473 K, after the reduction treatment, the gas flow was changed to a mixture of 2% C₂H₂ and 20% H₂ balanced with helium at a total flow rate of 50 $\text{cm}^3 \text{min}^{-1}$ and the time on stream was 9 h to evaluate the stability of the catalyst. For the temperature-programmed experiments, after reduction, the temperature was reduced to 300 K in 20 $\text{cm}^3 \text{min}^{-1}$ helium flow and then the gas flow was changed to the same composition as in the isothermal experiments. The temperature was increased in 50 K steps at 10 K min^{-1} . In each step, the composition of the gas flow was analysed after 30 min of stabilization.

The conversion on acetylene ($X_{\text{C}_2\text{H}_2}$) was calculated using the following equation:

$$X_{C_2H_2}(\%) = \frac{C_2H_2(feed) - C_2H_2}{C_2H_2(feed)} \quad (1)$$

Where $C_2H_2(feed)$ is the concentration of acetylene on the feed and C_2H_2 is the concentration of acetylene in the product stream. The selectivity in ethylene formation ($S_{C_2H_4}$) was calculated as follows:

$$S_{C_2H_4}(\%) = \frac{C_2H_4}{C_2H_2(feed) - C_2H_2} \quad (2)$$

where C_2H_4 is the concentration of ethylene in the product stream.

The Turnover Frequency (TOF) was calculated as:

$$TOF = \frac{\text{No. of } C_2H_4 \text{ molecules formed}}{\text{No. of exposed Pd sites on catalyst} \times \text{time}} \quad (3)$$

The activation energy (E_a) for acetylene hydrogenation under the established conditions for the tested samples was calculated from the Arrhenius plot as:

$$E_a = -\text{slope}(\text{Arrhenius plot}) \times R \quad (4)$$

where R is the gas constant.

2.4 Computational modeling details

The structures and energies of the reactant, transition, and product states in acetylene hydrogenation over an alumina-supported Pd cluster were calculated using the density functional theory (DFT) methods as implemented in the CP2K program package [29,30]. All calculations were carried out spin-polarized within the generalized gradient approximation (GGA) using the Perdew, Burke, and Ernzerhof (PBE) exchange-correction potential [31] and analytical pseudopotentials of the type suggested by Goedecker, Teter, and Hutter (GTH) [32]. The Kohn-Sham wave functions were expanded in a double-zeta valence polarized (DZVP) basis set [33] which was optimized based on molecular properties. An auxiliary plane-wave basis with a 600 Ry kinetic energy cutoff was used to describe the electron density of valence electrons [34]. Only the Γ -point was employed for Brillouin zone integration as the model systems are laterally large and the alumina substrate (slab) is an insulator. The DFT-D3 method with the standard parameters suggested by Goerigk and Grimme was employed to correct the dispersion interaction [35]. Bader analysis of effective charges on atoms was used to determine the charge transfer [36,37], and the reaction paths were calculated using the climbing-image nudged elastic band (CI-NEB) method [38].

A periodic slab model was used for the support by cleaving a bulk γ -Al₂O₃ model [39] in the (100) direction. The Al₂O₃(100) support was chosen as a four-layer (4 × 3) slab (in total 480 atoms, lateral size 22.33 × 25.19 Å²) and a vacuum spacing of at least 24 Å thickness in the vertical direction. The top two atomic layers were allowed to relax during the simulations while the bottom two layers were fixed. Here, a Pd₃₀ cluster with the square-base pyramidal structure was chosen as a representative model catalyst structure. Previously, the same structure with 30 Pd atoms (*fcc*) was used for Pd and Pd–O clusters based on the correspondence with electron microscopy analysis [40]. To justify the Pd₃₀/Al₂O₃ model as a representative choice, a larger model catalyst composed of a pyramidal Pd₅₅ cluster and an Al₂O₃(100) support with (5 × 3)-four-layer-slab (600 atoms, lateral size of 27.33 × 25.19 Å²) has been tested. After optimization, Pd₅₅ still displays the pyramid-like configuration with a base dimension of 10.71 × 10.78 Å². The nearest distances of cluster images are 16.6 and 14.4 Å in lateral directions, large enough to avoid interactions between cluster images, as imposed by periodic boundary conditions. The situation is comparable to the Pd₃₀/Al₂O₃ model where the corresponding image distances are 14.3 and 17.2 Å. For these two model structures, our DFT calculations reveal that the differences for acetylene adsorption energy (0.06 eV) and Bader charge on acetylene molecule (0.01*e*) are marginal. Meanwhile, the computational cost of the larger Pd₅₅/Al₂O₃ model is more than an order of magnitude more expensive. Thus, we consider the Pd₃₀/Al₂O₃ model structure both as feasible and representative for reaction modelling. Here, we need to declare that a larger model catalyst would need a much larger substrate to suppress cluster-cluster interactions due to periodic boundary conditions. This would lead to model structures of several thousands of atoms (most of them in the substrate) which is not feasible for DFT simulations in this context.

For acetylene hydrogenation over **Pd₃₀/Al₂O₃(100)** it was assumed that atomic hydrogen is already available on the catalyst surface (See Supporting Information). Based on the co-adsorption configuration of H* + H*, the adsorption sites of C₂H₂ and C₂H₄ were optimized by considering different sites on the cluster surface. Here, the adsorption energy (E_{ads}^2) was calculated as

$$E_{ads}^2 = E(adsorbate) + E(Pd_{30}(H)_2/Al_2O_3) - E(adsorbate + Pd_{30}(H)_2/Al_2O_3) \quad (5)$$

where $E(Y)$ is the total energy of the corresponding system Y .

Microkinetic simulations were performed based on data (parameters) from DFT calculations over the **Pd₃₀/Al₂O₃(100)** model catalyst to study the acetylene hydrogenation under varying conditions [41–43]. The full details of the microkinetic model have been explained by Ma *et al.* [42]. The simulations were carried out at temperatures from 300 to 500 K, atmospheric pressure

and feed composition of 2% C₂H₂ and 20% H₂. The kinetic values were estimated once the simulations were equilibrated to a steady state.

The acetylene conversion ($X_{C_2H_2}$) and ethylene formation selectivity ($S_{C_2H_4}$) were calculated as

$$X_{C_2H_2} = \frac{(R_{C_2H_4} + R_{C_2H_6})}{R_{C_2H_2}} \quad (6)$$

$$S_{C_2H_4} = \frac{R_{C_2H_4}}{(R_{C_2H_4} + R_{C_2H_6})} \quad (7)$$

where R refers to the reaction rate for the formation of the corresponding species.

3. Results

3.1 Characterization results

A 5% Pd on Al₂O₃ sample (**Pd/Al₂O₃ as-synthesized**) was prepared by flame spray pyrolysis (FSP), characterized, and tested for acetylene semi-hydrogenation reaction to achieve a basic understanding of the catalytic semi-hydrogenation of acetylene to ethylene on basic model systems. The powder XRD pattern of **Pd/Al₂O₃ as-synthesized** (Figure 1) shows the characteristic peaks of cubic Al₂O₃ corresponding to the support, and the presence of PdO is confirmed by the presence of a peak at 2θ of ca. 34°.

Figure 1: XRD pattern of the as-synthesized Pd/Al₂O₃ catalyst. Red lines: PdO; Black lines: Al₂O₃.

By imaging using high-angle annular-dark-field technique in scanning transmission electron microscopy (HAADF–STEM), PdO nanoparticles are observed to be uniformly anchored on the Al₂O₃ support (Figure 2a). Statistical measurements reveal that sizes of the crystalline PdO particles on the **Pd/Al₂O₃ as-synthesized** sample are in the 1–5 nm range, and the Al₂O₃ supports have diameters in the 10–35 nm range. In Figure 2b, close inspection of the morphology reveals that most of the PdO particles have elongated shapes and form agglomerates.

Figure 2: Low (a) and medium (b) magnification HAADF-STEM image of the as-synthesized Pd/Al₂O₃ catalyst, respectively.

In addition to the XRD pattern, analysis by X-ray photoelectron spectroscopy (XPS) also reveals that the **Pd/Al₂O₃ as-synthesized** material contains Pd catalyst particles in their terminal PdO oxidation state. This conclusion is supported directly by the observed binding energy (BE) of the Pd 3d_{5/2} component at 336.9 eV (Figure 3, top) [44]. The as-synthesized nature of this PdO oxidation state is indicated by the minimal changes in the XPS signatures of Pd 3d and C 1s produced by intentionally oxidizing the as-synthesized sample (Figure 3, middle). In order to characterize the sample as it is used for the catalytic testing, XPS analysis was also performed after the reduction of the sample (**Pd/Al₂O₃ reduced**). In contrast to the as-synthesized sample, under reducing conditions the dominant Pd 3d_{5/2} component shifts to 335.3 eV (purple in Figure 3, bottom), i.e., into the BE range of 335.1–335.4 eV previously reported [44,45] for metallic Pd. Furthermore, the chemistry of the associated organic material (solid symbols in C 1s region, Figure 3) also undergoes an apparent reduction from oxidized to aliphatic (red and blue C 1s components in Figure 3, respectively) [25].

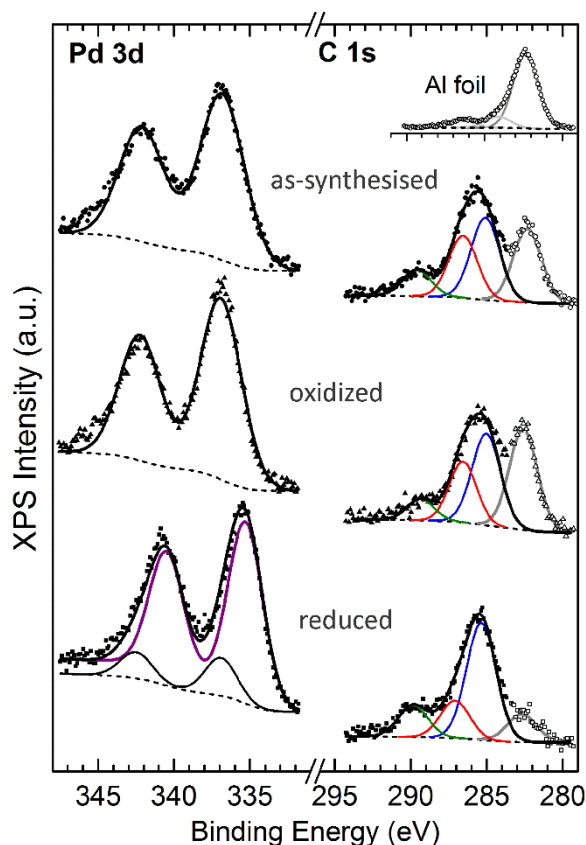

Figure 3: High-resolution XPS data for Pd 3d and C 1s regions. Supported-catalyst powders were measured as-synthesized (**Pd/Al₂O₃ as-synthesized**) and after oxidation or reduction treatments (**Pd/Al₂O₃ reduced**) (top-to-bottom). Differential charging produced a consistent 2.5 eV shift between aliphatic C 1s components corresponding to the supported-catalyst particles (blue lines, solid symbols) and Al-foil substrate (grey lines, open symbols, cf. top-right inset). Binding energy is presented after a correction (uniformly applied for all the catalyst samples), which placed the reference aliphatic C 1s peak (blue lines) at 285.0±0.2 eV. Symbols: raw data; thick lines: overall fits; thin colored lines: fits of individual components; dashed lines: background.

To characterize the active surface area of the catalyst, H₂ chemisorption was performed, on **Pd/Al₂O₃ reduced**, and the results are summarized in Table 1. The average palladium particle size (d_M) determined by hydrogen titration is approximately 6 nm, while the particle size determined by HAADF-STEM is 2.85 nm. The palladium dispersion (D_M) is 19% and the metallic surface area (S_M) is 83 m² g⁻¹. The BET specific surface area (S_{BET}), total pore volume (V_p) and pore width (d_p) of the **Pd/Al₂O₃ as-synthesized** catalyst were determined by N₂ physisorption, and the results are summarized on Table 1. The sample presents a surface area of 118 m² g_{cat}⁻¹, a total pore volume of 0.3 cm³ g_{cat}⁻¹ and a pore width of 2 nm.

Table 1: Textural properties of the as-synthesized Pd/Al₂O₃ sample.

	Amount of surface-bound H ₂ ^a (μmol g _{cat} ⁻¹)	D _M ^a (%)	S _M ^a (m ² g _{cat} ⁻¹)	d _M ^a (nm)	d _M ^b (nm)	S _{BET} ^c (m ² g _{cat} ⁻¹)	V _p ^c (cm ³ g _{cat} ⁻¹)	d _p ^c (nm)

3.2 Catalytic measurements for acetylene semi-hydrogenation reaction

Figure 4 presents the catalytic measurements results, as a function of temperature and time on stream, of acetylene semi-hydrogenation reaction on **Pd/Al₂O₃ reduced** and **Pd/Al₂O₃_Ref reduced**, both reduced *in-situ*; in this sub-section, these samples will be denoted as **Pd/Al₂O₃** and **Pd/Al₂O₃_Ref**, respectively. Figure 4a presents the Arrhenius plot of ethylene formation turnover frequency (TOF), from which the activation energy of acetylene hydrogenation is determined. Figure 4b shows the variation of acetylene conversion ($X_{C_2H_2}$) and ethylene formation selectivity ($S_{C_2H_4}$) with temperature for both samples tested and Figure 4c shows the same parameters as a function of time on stream.

Both samples display an increase in acetylene conversion and ethylene selectivity with temperature: In the case of the reference sample (**Pd/Al₂O₃_Ref**), $X_{C_2H_2}$ increases from 23% at 325 K to 92% at 500 K and $S_{C_2H_4}$ increases from 34% at 325 K to 56% at 500 K. For **Pd/Al₂O₃**, $X_{C_2H_2}$ increases from 12% at 325 K to 97% at 500 K and $S_{C_2H_4}$ increases from 42% at 325 K to 62% at 470 K. **Pd/Al₂O₃** behaves similarly to the reference sample, with somewhat higher selectivity for ethylene formation, for the tested temperatures. Regarding the stability, evaluated with the variation of $X_{C_2H_2}$ and $S_{C_2H_4}$ over time (Figure 4c), both samples show similar $X_{C_2H_2}$ values at 473 K over the tested time on stream, which decreases from 99% to 83% in the case of **Pd/Al₂O₃** and from 97% to 85% for **Pd/Al₂O₃_Ref**, after 9 h. In terms of $S_{C_2H_4}$, the value remains constant over 9 h of time on stream for both samples, with **Pd/Al₂O₃** showing a higher selectivity ($\approx 70\%$) than **Pd/Al₂O₃_Ref** ($\approx 60\%$).

The turnover frequency of ethylene formation was determined experimentally for the different temperatures tested and it increases with temperature, for both samples, reaching a value of 5 s⁻¹ and 3 s⁻¹ at 500 K for **Pd/Al₂O₃** and **Pd/Al₂O₃_Ref**, respectively. From the Arrhenius plot (Figure 4a) it is possible to determine the activation energy (E_a) for acetylene hydrogenation under the established conditions for the tested samples. Sample **Pd/Al₂O₃** exhibits an E_a of 5.0 ± 0.7 kcal mol⁻¹, while **Pd/Al₂O₃_Ref** exhibits an E_a of 3.5 ± 0.6 kcal mol⁻¹.

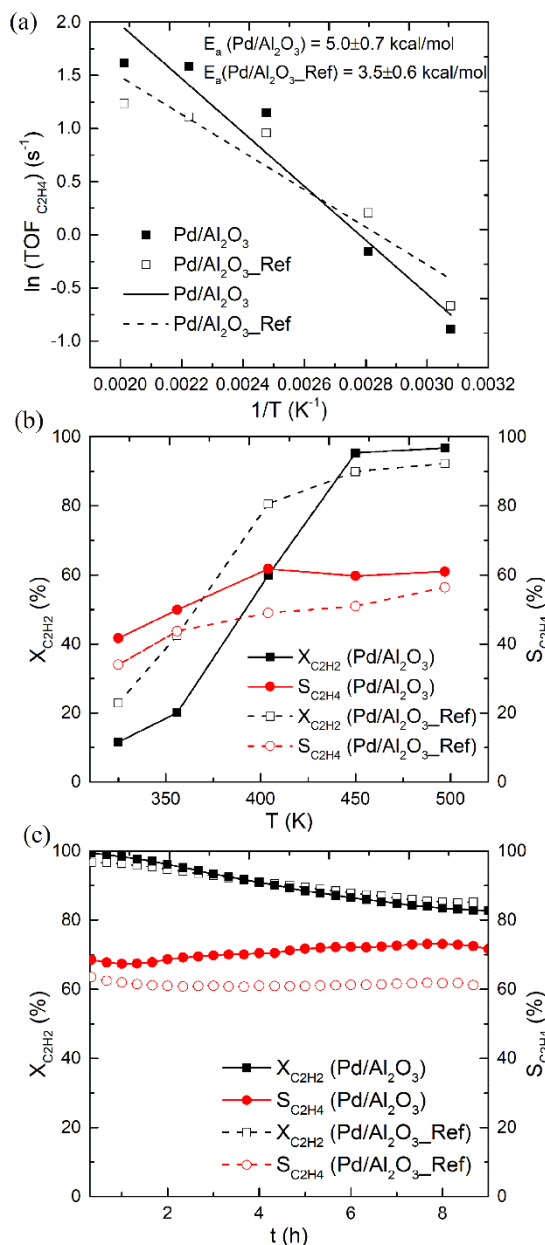

Figure 4: Catalytic measurement results as a function of the temperature and time on stream of acetylene semi-hydrogenation reaction on Pd/Al₂O₃ and Pd/Al₂O₃_Ref. The Arrhenius plot of ethylene formation turnover frequency (TOF) (a); acetylene conversion ($X_{C_2H_2}$) and ethylene formation selectivity ($S_{C_2H_4}$), as a function of the temperature (b) and time on stream (c).

3.3 DFT simulations and microkinetic modelling

3.3.1 Cluster-surface interaction. Figure 5 gives the optimized model catalyst structure of Pd₃₀/γ-Al₂O₃(100). Upon optimization, the Pd₃₀ cluster still shows the pyramid-like structure with a base dimension of 8.03 × 7.95 Å² and average height of 5.78 Å. The optimized average Pd-Pd bond length is 2.76 Å, slightly larger than the 2.75 Å value in bulk Pd. The bond distances between the cluster base and support outermost layer vary in the range of 2.13–2.23 Å (Pd-O).

The calculated cluster adsorption energy (E_{ads}^1) of Pd₃₀ is 12.46 eV (0.195 eV Å⁻²). Here, E_{ads}^1 is defined as

$$E_{ads}^1 = E(Pd_{30}) + E(Al_2O_3) - E(Pd_{30}/Al_2O_3) \quad (8)$$

where $E(X)$ is the total energy of the related system X . The Bader charge analysis reveals that the Pd₃₀ cluster gains 1.64e of electron density in total, originating from the Al₂O₃ substrate, which makes the negatively charged catalyst prone to attract reactant molecules.

Figure 5: Model structure (side-view and top-view) of a pyramidal Pd₃₀ cluster on γ -Al₂O₃ (100) surface. Color key: Pd, dark green; O, red; Al, pink.

The projected density of states (PDOS) of electronic structure, charge density difference (CDD), and HOMO–LUMO orbital distributions are displayed in Figure 6. PDOS (Figure 6a) shows the projection of Kohn-Sham single-particle states onto atomic s-, p- and d-components in the catalyst and support, respectively. At the Fermi energy, the weight of PDOS is significant on the cluster (Pd d-orbitals), while the support (insulator) exhibits a band-gap structure. In addition, the d-band center of Pd₃₀ cluster, relative to the cluster Fermi energy, is calculated to be -2.00 eV, close to the experimental d-band centers in extended (bulk) Pd surfaces of -2.02 eV [46] and -2.09 eV [47]. The CDD visualization (Figure 6b) displays a significant charge accumulation and depletion at the interface between the Pd₃₀ cluster and Al₂O₃ substrate, providing more insight for the observed charge transfer. In particular, the accumulated charge is distributed around the cluster perimeter. Furthermore, the HOMO and LUMO orbital distributions (Figure 6b) show that both states that are relevant to chemical reactivity are mainly delocalized within the Pd₃₀ cluster, with very small weight on the Al₂O₃ support.

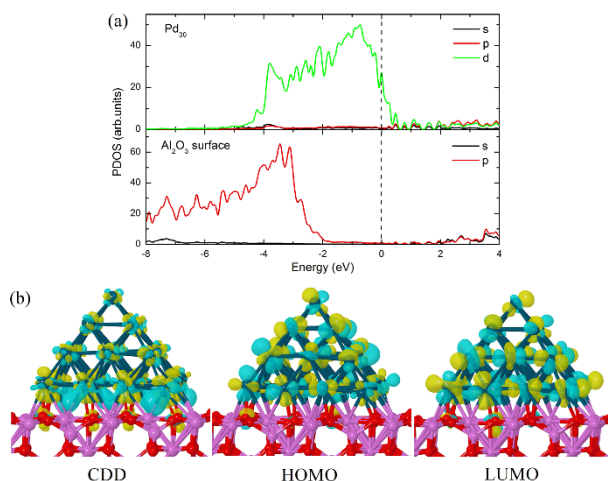

Figure 6: The electronic properties of $\text{Pd}_{30}/\text{Al}_2\text{O}_3(100)$ system: (a) Projected density states (PDOS) on the atomic s-, p- and d- orbitals in the cluster and support, respectively. The vertical line indicates the Fermi level. (b) Side view of charge density difference (CDD) and HOMO–LUMO orbitals. The yellow and aqua colors for CDD represent charge depletion and accumulation, respectively. For HOMO/LUMO these colors represent the different signs of the wavefunction. The isosurface values are $\pm 0.002 e a_0^{-3}$ for CDD and $\pm 0.01 e a_0^{-3}$ for HOMO and LUMO.

3.3.2 Acetylene hydrogenation. The optimal adsorption site of the H_2 molecule was mapped by testing H_2 on different sites of the Pd_{30} cluster surface, and the results are presented in supplementary material. Figure 7 displays the structures of the initial state (IS), transition state (TS), intermediate state (IM), and final state (FS), and the energy diagrams along the hydrogenation pathways of acetylene to ethylene (Figure 7a) and consecutive unwanted ethylene to ethane (Figure 7b). At IS1, C_2H_2 binds on the hollow site of the Pd_{30} surface with $E_{ads}^2 = 2.11 \text{ eV}$. The adsorbed C_2H_2 molecule receives $0.16e$ electron density from the catalyst. During the acetylene hydrogenation reaction, C_2H_2 is first hydrogenated to C_2H_4 by attaching two H atoms through TS1, IM1, and TS2 along the reaction pathway as shown in Figure 7a. In the first transition state (TS1), H atom moves to the adjacent Pd top site from its original hollow site with a H–Pd and H–C bond of 1.57 and 1.65 Å, respectively. At the same time, the orientation of C_2H_2 also changes slightly, and the activation barrier is 0.72 eV (TS1). After this, the first intermediate state (IM1) of C_2H_3 is formed with an exothermic energy of 0.05 eV. The activation barrier for the second H atom (TS2) is 0.75 eV with H–Pd and H–C bond lengths of 1.57 and 1.88 Å, respectively. The first product molecule of C_2H_4 is formed in FS1 by the H atom binding to C_2H_3 and the reaction energy is -0.36 eV .

Following the first-step hydrogenation of C_2H_2 to C_2H_4 , two additional H atoms were placed on the same hollow sites of the Pd_{30} surface. C_2H_4 prefers to bind on a bridge site of the $\text{Pd}_{30}(\text{H})_2$ surface with the adsorption energy of 1.33 eV and a net charge of $-0.05e$. Next, C_2H_4 is hydrogenated to the final product (FS2) of C_2H_6 by attaching H atoms one-by-one. The reaction pathway in Figure 7b includes two transition states with activation barriers of 0.92 eV (TS3) and

0.81 eV (TS4) and one intermediate (IM2, C₂H₅) with reaction energy of 0.26 eV. The corresponding higher activation barriers give the first indication for ethylene selectivity. The final product of C₂H₆ (FS2) is generated with an exothermic energy of -0.10 eV. The C–C and C–H bond lengths of the C₂H₆ molecule are 1.53 and 1.10 Å (1.54 and 1.11 Å in gas-phase), respectively.

Figure 7: Structures of the initial state (IS), transition state (TS), intermediate state (IM), and final state (FS), and the energy diagrams along the hydrogenation pathways of (a) acetylene to ethylene ($\text{C}_2\text{H}_2 + \text{H}^* + \text{H}^* \rightarrow \text{C}_2\text{H}_4^*$), and (b) ethylene to ethane ($\text{C}_2\text{H}_4 + \text{H}^* + \text{H}^* \rightarrow \text{C}_2\text{H}_6$) over $\text{Pd}_{30}/\text{Al}_2\text{O}_3(100)$. The energy diagrams display the reactants/products and a cluster (111)-facet (only fraction of the cluster). The geometrical parameters (in Å) are also given. The symbol * refers to the atom or molecule being adsorbed on the catalyst. Color key: Pd, dark green; H, aqua; C, gray; O, red; Al, pink.

3.3.3 Microkinetic simulations. Figure 8 displays the microkinetic results for the temperature dependence of the Arrhenius plot of ethylene formation turnover frequency (TOF), acetylene conversion ($X_{\text{C}_2\text{H}_2}$) and ethylene formation selectivity ($S_{\text{C}_2\text{H}_4}$), and the surface coverages of hydrogen (θ_{H}), and acetylene ($\theta_{\text{C}_2\text{H}_2}$). The simulations show that the TOFs of ethylene increase with temperature. The apparent activation energy (E_a) of acetylene hydrogenation is $8.8 \pm 0.6 \text{ kcal mol}^{-1}$ by fitting the Arrhenius plot in Figure 8a. Here, we need to emphasize that this

apparent activation energy is different from the DFT-calculated activation barriers in the elementary reaction steps, as shown in Figure 7.

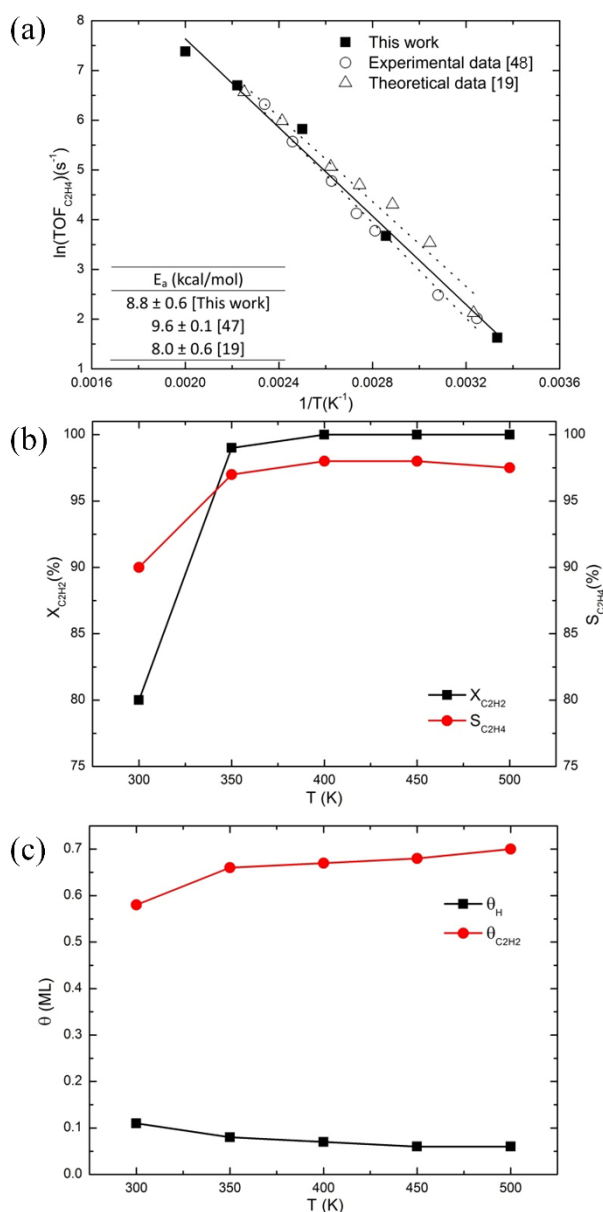

Figure 8: Microkinetic modeling results as a function of the temperature in acetylene hydrogenation over $\text{Pd}_{30}/\text{Al}_2\text{O}_3(100)$. (a) Arrhenius plot of ethylene formation turnover frequency (TOF), (b) Acetylene conversion ($X_{\text{C}_2\text{H}_2}$) and ethylene formation selectivity ($S_{\text{C}_2\text{H}_4}$), and (c) surface coverage of hydrogen (θ_{H}) and acetylene ($\theta_{\text{C}_2\text{H}_2}$).

The simulated results of $X_{\text{C}_2\text{H}_2}$ and $S_{\text{C}_2\text{H}_4}$ as a function of temperature are plotted in Figure 8b. Both increase with the temperature between 300 and 500 K; $X_{\text{C}_2\text{H}_2}$ increases from 80% at 300 K to 100% at 400 K, and $S_{\text{C}_2\text{H}_4}$ increases from 90% at 300 K to 99% at 470 K. The formation of C_4 and C_6 byproducts are not included in the current simulations, which can lower the ethylene selectivity at the lower temperature [48].

The surface coverages of all species were also examined, and those for hydrogen (θ_{H}) and acetylene ($\theta_{\text{C}_2\text{H}_2}$) are plotted as a function of temperature in Figure 8c. They exhibit opposite behavior with increasing temperature: θ_{H} decreases from 0.11 ML at 300 K to 0.06 ML at 450 K, while $\theta_{\text{C}_2\text{H}_2}$ increases from 0.58 ML at 300 K to 0.70 ML at 500 K. Furthermore, the surface coverages of vinyl, ethylene, and ethyl (not shown) are very low in the range of the temperatures considered herein.

4. Discussion

Here, we present a combined approach using both experimental and theoretical studies to develop and validate a theoretical model for predicting behavior of catalysts. Typically, it is possible to find overlapping experimental and theoretical studies in the literature, however, combined approaches are rather rare. A Pd/Al₂O₃ catalyst (**Pd/Al₂O₃ as-synthesized**) was synthesized using the flame spray pyrolysis method, a typical method for catalyst preparation, and it was used as standard catalyst, after *in situ* reduction (**Pd/Al₂O₃ reduced**), to test the theoretical model obtained through computational simulations. The performance of a representative Pd₃₀ cluster was simulated and it was compared with the real Pd catalyst on alumina to confirm the success of the developed model.

The characterization of the **Pd/Al₂O₃ as-synthesized** sample by XRD showed that the Pd catalyst nanoparticles are in the PdO state (Figure 1), which is expected due to oxidation of the catalysts during synthesis because of high oxidation conditions present in the flame. This result was confirmed by XPS analysis with the binding energy (BE) of the Pd 3d_{5/2} (Figure 3) which is in excellent agreement with the BE of 336.8 eV previously reported by Brun *et al.* [44] for a reference PdO powder. However, as shown from the XPS results, after reduction (**Pd/Al₂O₃ reduced**), the dominant Pd 3d_{5/2} component is in the range of 335.1–335.4 eV, previously reported [44,45] for metallic Pd, which means that the catalysts nanoparticles are metallic Pd after *in situ* reduction and before reaction. XPS confirms the reduction of the associated organic material from oxidized to aliphatic, thus, supporting the conclusion that both Pd and organic constituents of the sample become oxidized during synthesis rather than due to the subsequent exposure to air. We note that the 0.5–3 eV higher BE values reported for the metallic and oxidized Pd supported on insulating (e.g., alumina [49] or zeolite [50]) particles may result from the ambiguous nature of the C 1s component assigned as the aliphatic-carbon BE reference: The possible artifacts due to differential charging are highlighted by the 2.5 eV separation explicitly observed in this work between the spectral signatures derived from the Al-foil substrate and the supported catalyst particles (open and solid symbols in Figure 3, respectively).

The HAADF–STEM shows, as expected, that the catalyst prepared using flame spray pyrolysis (**Pd/Al₂O₃ as-synthesized**) yielded spherical PdO particles with an average size of 2.85 nm

(Table 1), uniformly distributed on the supporting material (Figure 2). The obtained average size and particle shape is similar to those reported, for example, by Strobel *et al.* [51] for a Pd on alumina sample also prepared by FSP, which presents spherical shaped Pd nanoparticles with an average size of 2.7 nm. The structure and morphology of the support were maintained after the deposition of the Pd nanoparticles (Table 1). The specific surface area (S_{BET}), pore volume (V_p) and pore diameter (d_p) are similar for the used Al_2O_3 support and for the **Pd/ Al_2O_3 as-synthesized** catalyst, which confirms that the deposition of the Pd nanoparticles did not alter the microstructure of the support. Similarly to the Pd particle size, the microstructure of our sample is comparable to the properties of the catalyst prepared by Strobel *et al.* [51], which had a specific surface area of $120 \text{ m}^2 \text{ g}_{\text{cat}}^{-1}$.

The particle sizes were determined both by HAADF–STEM, on the **Pd/ Al_2O_3 as-synthesized sample**, and H_2 chemisorption on the **Pd/ Al_2O_3 reduced** catalyst (Table 1): the particle size obtained from H_2 chemisorption is higher. This discrepancy is due to the different weighting of the two procedures: chemisorption determines the surface-area weighted diameter, while HAADF–STEM determines the number-average diameter. Importantly, the value determined by chemisorption provides valuable information for heterogeneous catalysis, as it is related to the active metallic surface area. The values of Pd dispersion and particle size obtained by H_2 chemisorption (Table 1) are comparable to those obtained by Strobel *et al.* [51] using CO chemisorption.

The results obtained for the conversion and selectivity of the **Pd/ Al_2O_3 reduced** and **Pd/ Al_2O_3 _Ref reduced** samples (Figure 4) are similar, which confirms that **Pd/ Al_2O_3 reduced** can be used as a model catalyst since it behaves similarly to the commercial reference sample. In addition, the obtained results agree with those found in the literature [12,48] in the range of the tested temperatures. In this work, to simplify the theoretical simulations, a simplified gas mixture was used, neglecting the large excess of ethylene common in the industrially relevant feed composition (non-competitive conditions). Thus, the results were compared to studies where the excess of ethylene was also omitted. Table 2 presents a comparison of the experimental results obtained in this work with those reported in the literature for similar catalysts.

Table 2: Comparison of catalyst performance, determined experimentally (Exp) and theoretically (Theo).

Catalyst	$X_{\text{C}_2\text{H}_2}$ (%) at 450K	$S_{\text{C}_2\text{H}_4}$ (%) at 450K	E_a (kcal mol ⁻¹) ¹	m_{cat} (mg)	Feed Composition ($\text{C}_2\text{H}_2:\text{H}_2$)	Ref.

Osswald *et al.* [12] tested a Pd on Al₂O₃ reference catalyst which achieved a maximum conversion at 450 K, and a similar temperature dependence of activity was observed in the current work (Figure 4). The activity reported by Osswald *et al.* at 450 K is lower ($\approx 80\%$) than that obtained for both samples here (95% and 90%). The catalysts studied by Osswald *et al.* exhibit higher selectivity in the 350–500 K interval, ranging from 60% to 80% [12]. Molero *et al.* [48], tested a palladium foil sample for acetylene semi-hydrogenation where the selectivity increased drastically from approximately 30% at 300 K to 94% at 470 K. Considering the selectivity and conversion results, the sample prepared and tested in this study exhibits an overall trend similar to the results found in the literature, however, with slightly different selectivity [12,48]. We note that these differences in the selectivity and conversion values can be due to differences in the experimental conditions, i.e., different feed composition and mass of catalyst used. Osswald *et al.* [12] used a feed composition of 2% acetylene and 4% hydrogen in helium and 0.5 mg of catalyst, while Molero *et al.* [48] performed the reaction with a ratio of acetylene to hydrogen of 1:1.

In terms of stability, the selectivity values in Figure 4c agree with previous studies [12], but the conversion rate has a smaller decrease compared to the study of Osswald *et al.* [12], where the stability of a reference Pd on alumina catalyst was also tested and the conversion decreased from 100% to around 20% after 9 h, while the selectivity was approximately stable at 60% [12]. As above, we note that the reaction conditions used in Ref [12] are different from ours.

Our computational studies suggest a comparable catalytic activity for acetylene hydrogenation on a Pd₃₀ cluster and on Pd surfaces, as expected based on the similar d-band centers of these systems (Figure 6a). However, the microkinetic simulations (Figure 8) predict a higher activity and selectivity for the Pd₃₀ clusters, and the predicted trends agree with those obtained in the experimental results (Figure 4). The selectivity for ethylene determined in the microkinetic simulations agrees well with the previous results for simulations [19] and experiments for surfaces [48] in the same range of temperatures. The quantitative differences between the experiments (Pd/Al₂O₃) and theory (Pd₃₀/Al₂O₃(100)) can be explained by the particle size: the clusters in Pd₃₀/Al₂O₃(100) are considerably smaller than the Pd nanoparticles on Pd/Al₂O₃, which explains the lower experimental selectivity. The larger Pd nanoparticles favor the formation of the β -hydride phase, which supplies active hydride species to surfaces resulting in full hydrogenation of acetylene to ethane, thus decreasing the ethylene selectivity [52,53]. Furthermore, our microkinetic model has been parameterized at low coverage which may affect the results.

The computed activation energy over Pd₃₀/Al₂O₃(100) (8.8 ± 0.6 kcal mol⁻¹) is comparable to the experimental value obtained by Molero *et al.* [48], of 9.6 ± 0.1 kcal mol⁻¹ over a clean Pd foil,

and with the computed by Mei *et al.* [19] value, of 8.0 ± 0.6 kcal mol⁻¹ over Pd(111), at the conditions of $P(\text{H}_2) = P(\text{C}_2\text{H}_2) = 100$ Torr and the temperature range of 300–500 K, but the activation energy obtained experimentally for the **Pd/Al₂O₃ reduced** sample is slightly lower (5.0 ± 0.7 kcal mol⁻¹). Again, these values are sensitive to the experimental conditions (feed composition), catalyst itself (film, nanoparticle), as well as synthetic history.

Figure 9 shows the comparison between the acetylene conversion ($X_{\text{C}_2\text{H}_2}$) and ethylene formation selectivity ($S_{\text{C}_2\text{H}_4}$) results, as a function of the temperature, determined experimentally and theoretically. It can be observed that the results obtained experimentally with the **Pd/Al₂O₃ reduced** catalyst qualitatively agree with the microkinetic simulations based on parameters from extensive DFT calculations over a **Pd₃₀/Al₂O₃(100)** model catalyst. The predicted and experimental conversions agree well at temperatures above 450 K, while selectivities and conversions at lower temperatures are different, apart from the agreement in the general trend of increasing of activity and selectivity with temperature. The mismatch between theory and experiment may be due to simplifications used in the modeling where the dissolution of hydrogen and carbon in the Pd subsurface region were not considered [52]. More expensive calculations where the structure of Pd cluster is flexible and can be refined are required to improve the theoretical results. Nevertheless, the good agreement at high temperatures show that the model used in this study can be used for fast screening of potential catalysts, especially of intermetallic catalysts with covalent bonding where the dissolution of hydrogen or carbon is suppressed [24]. Conversely, the high selectivity predicted by the theory indicates that novel material designs that attempt to minimize the dissolution of hydrogen and carbon in Pd should be considered for increasing the selectivity of the practical catalysts.

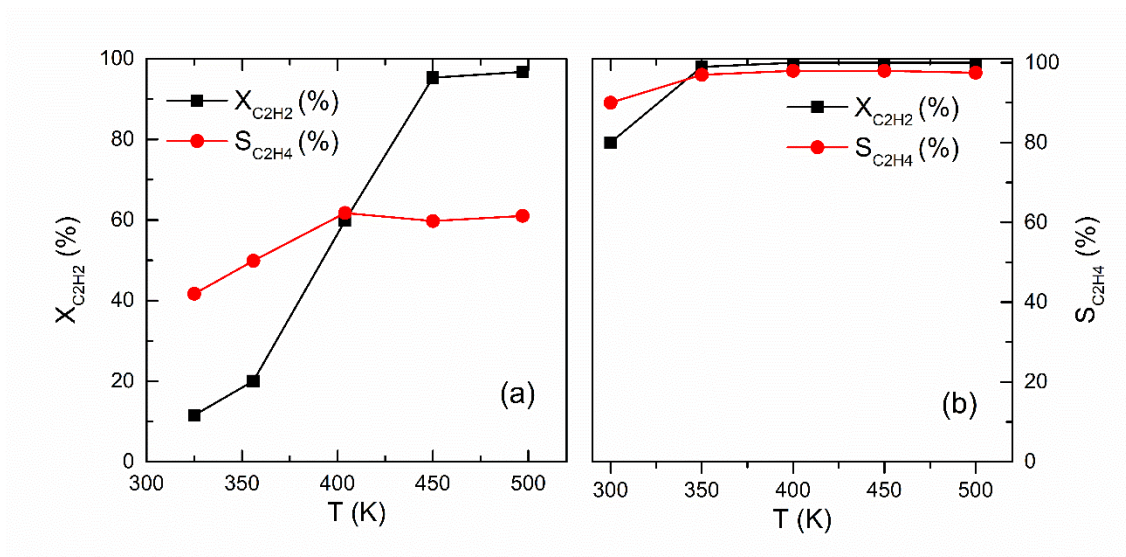

Figure 9: Acetylene conversion ($X_{C_2H_2}$) and ethylene formation selectivity ($S_{C_2H_4}$), as a function of the temperature, determined experimentally (a) and theoretically (b).

5. Conclusions

It has been shown that by high-throughput FSP method it is possible to prepare large quantities of active and selective Pd catalyst for the acetylene semi-hydrogenation reaction. In particular, the prepared catalyst, reduced *in situ*, achieves a conversion of acetylene of 97% at 500 K and a selectivity to ethylene of 62% at 470 K. More importantly, these results correlate with the microkinetic simulations based on parameters from extensive DFT calculations over a Pd₃₀/Al₂O₃(100) model catalyst. The insights gained from this direct comparison can be applied to a parallel computational screening of complex hydrogenation catalysts and synthesis and investigation of the most promising candidates, in the context of both the industrial polymerization process and the novel applications in the H₂ economy.
