#### Abstract

SUMMARY: This master thesis is a part of the WoodSol project, a research project coordinated by NTNU, Department of Structural Engineering. This study includes an investigation of the serviceability state issues on high-rise timber buildings. The buildings studied have a structural system where moment resisting frames are used for horizontal bracing in one direction. The bracing is enhanced by the stiffness from composite wood slabs. The work is limited to examine the acceleration, deflection and the fire capacity of the system.

The first part of the thesis describes wood as a construction material, and the requirements and design considerations for the structural system. The models investigated were based on two main designs. One simple design with rectangular footprint and one unsymmetrical, hence more complicated, T -shape design. The finite element program Abaqus was used for the modelling. A verification process was preformed to ensure the validity of the numerical simulations.

A parametric study was done to map the response and robustness of the structural system. For each model, properties of different building components, e.g. cross sections dimensions, the rotational stiffness in the connections and the boundary conditions were changed. Then, a modal analysis was done to find the dynamic properties of the models. The natural frequency and mass were used to calculate the acceleration and the structural factor, $\mathrm{c}_{s} \mathrm{c}_{\mathrm{d}}$, which is used to calculate the wind loads affecting the model. Both ULS and SLS load combinations have been checked, giving results for evaluating the fire design and the deflections in the top of the building, respectively.

Acceleration was found to be the governing requirement, which was expected based on previous work done on high-rise timber buildings. From the findings of this work, it can be concluded that it will be possible to build high-rise timber buildings using the structural system with moment resisting frames bracing the building in one direction. To meet the requirements for acceleration, deflection and fire capacity, modifications have to be done. Like adding extra mass, increasing column sections and connecting shafts to the structural system. With the right modifications, it is possible to build eight storey high buildings, and probably higher.

## Preface

This master thesis is a part of the 5-year study program, Civil and Environmental Engineering. This thesis is written at the Department of Structural Engineering at the Norwegian University of Science and Technology (NTNU), during the spring semester of 2017. The work done is a part of the research project WoodSol, Wood frame solutions for free space design in urban buildings, at NTNU.

The work consisted of doing numerical analysis and a parametric study of structural systems for a five to 10 storey timber building. The work has given us a greater understanding on structural systems in high-rise buildings, and the challenges and advantages for building with wood. We have learned more on the complexity of the peak acceleration calculation, and how the results depend on changes to the building through a parametric study. Due to little prior experience, a lot of time was spent learning the FEM-program Abaqus and we are now familiar with many of the programs functions and possibilities.

We are very grateful to supervisor Kjell Arne Malo and co-supervisor Haris Stamatopoulos for all the guidance and helpful discussions through the entire semester. Further we would like to thank the rest of the WoodSol group for help and inspiration, and hope our work is found useful. Finally, we would like to thank all our classmates for making the years here at NTNU so memorable.

## Abstract

This master thesis is a part of the WoodSol project, a research project coordinated by NTNU, Department of Structural Engineering. This study includes an investigation of the serviceability state issues on high-rise timber buildings. The buildings studied have a structural system where moment resisting frames are used for horizontal bracing in one direction. The bracing is enhanced by the stiffness from composite wood slabs. The work is limited to examine the acceleration, deflection and the fire capacity of the system.

The first part of the thesis describes wood as a construction material, and the requirements and design considerations for the structural system. The models investigated were based on two main designs. One simple design with rectangular footprint and one unsymmetrical, hence more complicated, T-shape design. The finite element program Abaqus was used for the modelling. A verification process was preformed to ensure the validity of the numerical simulations.

A parametric study was done to map the response and robustness of the structural system. For each model, properties of different building components, e.g. cross sections dimensions, the rotational stiffness in the connections and the boundary conditions were changed. Then, a modal analysis was done to find the dynamic properties of the models. The natural frequency and mass were used to calculate the acceleration and the structural factor, $c_{s} c_{d}$, which is used to calculate the wind loads affecting the model. Both ULS and SLS load combinations have been checked, giving results for evaluating the fire design and the deflections in the top of the building, respectively.

Acceleration was found to be the governing requirement, which was expected based on previous work done on high-rise timber buildings. From the findings of this work, it can be concluded that it will be possible to build high-rise timber buildings using the structural system with moment resisting frames bracing the building in one direction. To meet the requirements for acceleration, deflection and fire capacity, modifications have to be done. Like adding extra mass, increasing column sections and connecting shafts to the structural system. With the right modifications, it is possible to build eight storey high buildings, and probably higher.

## Sammendrag

Denne masteroppgaven er skrevet som en del av forskningsprosjektet WoodSol, som er ledet av NTNU ved Instituttet for konstruksjonsteknikk. Oppgaven innholder et studie av bruksgrensetilstanden til høyhus i tre, der et bæresystem basert på momentstive rammer bidrar til horisontal avstivning. Studiet er begrenset til å undersøke akselerasjonen, utbøyningen og brannkapasiteten til konstruksjonen.

Den første delen av oppgaven beskriver tre som konstruksjonsmateriale og går gjennom kravene konstruksjonssystemet må tilfredsstille. Modellene som er undersøkt er basert på to hoveddesign. Et enkelt, med et rektangulært fotavtrykk, og et mer komplekst og usymmertisk T-formet design. Abaqus, som er et program som utfører numeriske simuleringer, ble brukt til modellering og analyser. For å sikre korrekt modellering, ble det utført en verifiserinsprosess.

Et paramterstudie ble gjennomført for å kartlegge ytelsen og robustheten til bæresystemet. For hver modell er det blitt gjort endringer av egenskaper for utvalgte bygningskomponenter, og utført modale analyser for å finne dens dynamiske egenskaper. Modellens egenmoder og masse ble brukt til å regne ut akselerasjon, mens konstruksjonsfaktoren, $c_{s} c_{d}$, ble brukt til å regne ut vindlasten som modellene ble utsatt for. Lastkombinasjoner for både brudd- og bruksgrensetilstand er brukt til henholdsvis å vurdere bygningens brannkapasitet, og utbøyning i øverste etasje.

Akselerasjonskriteriet viste seg å være vanskeligst å nå. Dette var forventet, da tidligere arbeid som omhandler høyhus i tre har indikert det samme. Basert på resultater fra arbeidet med denne rapporten, kan man konkludere med at det er mulig å bygge høyhus i tre med konstruksjonssystemer som bruker momentstive rammer til avsivning i en retning. For å nå akseptable verdier for akselerasjon, utbøyning og brannkapasitet, kan modifikasjoner som å legge til masse i bygningen, øke søylers tverrsnittsstørrelser og koble en sjakt til det stabiliserende systemet gjøres. Med de riktige modifikasjonene kan man bygge åtte etasjers høyhus itre, og sannsynligvis høyere, med dette konstruksjonssystemet.

## Chapter 1

## Introduction

### 1.1 Starting point

This master thesis is a part the WoodSol project. The project is coordinated by NTNU, Department of Structural Engineering, and was started in 2016. The main goal of WoodSol is to develop industrialised structural solutions, based on rigid wooden frames, for use in urban buildings having five to 10 storeys open architecture [42].

The increasing urbanisation have created a demand for more high-rise buildings, but to meet the environmental challenges of today the building industry needs to cut their carbon emissions. A solution to this problem can be the use of more environmental friendly materials, like wood, which is considered to be carbon neutral. There has been a growing interest among developers and architects to use more wood products. A study conducted for Statshygg disclosed that there is a lack of knowledge and standardised solutions for high-rise timber buildings, which makes it a bigger risk to choose wood over more traditional and familiar structural systems based on concrete and steel [37]. For this to change, there needs to be developed industrialised structural concepts that are robust and flexible with low economic risk. Prior work done on high-rise buildings in timber, show that satisfying the serviceability limit state requirements can be challenging [40] [3]. A light material like wood can result in high accelerations and horizontal deflection at the top floor.

### 1.2 Objectives and limitations

This work includes studying several different building designs, where the structural system is based on the use of moment resisting frames. Their natural frequencies, mode shapes and response to wind load is evaluated. Subsequently looking at the acceleration, deflection and response to fire load. The objective of this master thesis is to develop an understanding, with help of a parametric study, of the global response in the serviceability limit state, and how the different geometries and change of parameters effect the results.

The focus of this work has been a global analysis of the serviceability limit state of the buildings, and it will not include

- seismic performance
- vertical deflection and response of the slabs
- detailing of solutions
- acoustic evaluation
- evaluation of erection and assembly
- Life Cycle Cost (LCC) and Life Cycle Analysis (LCA)

### 1.3 Approach and structure of thesis

The thesis starts with an overview of the requirements and design considerations. The relevant work done in WoodSol is presented, followed by some background on the use of wood as the material in a structural system. The typologies of the buildings are decided and the requirements they are to satisfy are presented. Then there is performed a verification of the numerical model. This to validate the simplifications of the model used for analysis in the finite element program Abaqus. The result from the analysis is presented for each model and discussed further, before some conclusive remarks are made. At last, some recommendations for further work are presented.

## Chapter 2

## Background

This chapter gives the basis for the structural system and the requirements that should be considered in the design and modelling process.

### 2.1 Typology

Some guidelines for the typology must be established as basis for the structural system. The typology of a building concerns its shape, height and footprint, as well as the need for open spaces and the sectioning of the building. These parameters are essential for how the structural system should be, deciding the placement of supporting elements and how the loads are carried through the building. Some examples of footprints are shown in Figure 2.1.

Figure 2.1: Examples of footprints

In this thesis, the premise for the building is to meet the volume market, focusing on residential and office buildings in urban areas. As the population is growing and more people move into cities, it is likely that cities develop towards getting a higher population density. To enable this, the cities need to be more compact, and this can be done by building higher or by adding storeys on top of existing buildings. The structural system should be robust and flexible to allow open architecture and future changes of
use, preferably with repetitive prefabricated elements and a symmetrical layout. If this is successful, the assembly of the building will be fast and uncomplicated. Variations as cantilever elements, balconies and different roof structures should be easily implemented to the simple and robust structural system. For future flexibility it is tried to use as few inner columns and shear walls as possible, creating big open spaces. Based on the prestudy done by the WoodSol project and the interviews done in the context of this thesis ${ }^{1}$, some constrains and guidelines are defined, see Table 2.1.

Table 2.1: Constrains of structural lay-out of components

| Number of storeys | 5 to 10 <br> stricter fire regulation over 8 storeys |
| :--- | :--- |
| Net storey height | $\min .2 .4 \mathrm{~m}$ (residential) <br> min. $2.6-2.7 \mathrm{~m}$ (offices etc.) |
| Span length of floor elements | 8 to 10 m |
| Maximum size of components <br> (due to transport) | width: 2.4 m <br> length: 35 m |

[^0]
### 2.2 Wood as construction material

Wood is an anisotropic material, meaning that the properties are dependent on directions. The stiffness in the longitudinal direction is $10-15$ times higher than the radial, and 20-30 times higher than the tangential [6]. The material directions are illustrated in Figure 2.2.

Figure 2.2: Material orientation of wood [7]

Wood is a material with high strength and stiffness compared to its weight. The modulus of elasticity ( E ) is low compared to steel and concrete, but the specific stiffness is similar to steel, see Table 2.2.

Table 2.2: Material properties for steel, concrete ${ }^{2}$ and wood [24]

| Material | E <br> $[\mathrm{MPa}]$ | $\rho$ <br> $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | Specific stiffness <br> $\mathrm{E} / \rho$ |
| :--- | :---: | :---: | :---: |
| Steel | 210000 | 7800 | 27 |
| Concrete | 35000 | 2400 | 14 |
| Wood (C24) | 11000 | 420 | 26 |

Construction elements where large portions of the load comes from its own self-weight, like slabs, will be a lot lighter using wood compared to concrete or steel. A building with low self-weigh is beneficial in urban areas, where the possibility for foundation can be limited, or when wanting to add more storeys on top of an existing building [32]. Development of more engineered wood products utilise the advantages of the material properties and make the use of wood more suitable for tall buildings.

[^1]

Figure 2.3: Construction materials in wood

## Glue Laminated Timber, GLT

Figure 2.3a shows a GLT beam. GLT, or glulam, consists of wood panel layers glued and compressed together. Either homogeneous, with the same strength in all layers, or in-homogeneous, with varying strength. The material properties are better than for construction timber and it is used for both buildings and bridges. Glulam beams can be curved, have large spans and be produced with almost any dimension of cross section. There are several big producers in Norway, among other, Moelven and Splitcon.

## Cross Laminated Timber, CLT

Figure 2.3b shows typical CLT panels. Developed in the 1990s, CLT created new opportunities for the use of wood as a building material [1]. CLT panels are normally composed with three, five or seven layers, connected with glue or wooden pegs and stacked in layers rotated 90 or 45 degrees with respect to each other. The layers can have different thickness and wood quality. The lay-up makes the panels able to better carry load in two directions, making them suitable as floor and wall panels. Total thickness is normally between 60 and 300 mm . The elements can have large cut-outs and are prefabricated with millimetres precision, cutting the installation time on site. There are some smaller producers of CLT elements in Norway, but for bigger projects the elements are today imported from manufacturers in Southern Europe ${ }^{3}$.

## Laminated Veneer Lumber, LVL

Figure 2.3c shows LVL products. LVL is a product of multiple 3 mm veneer layers, and is the strongest wood product on the marked [18]. Normally, all fibres are in the same

[^2]direction and the total thickness of a plate or beam is between 21 mm and 90 mm . MestäWood in Finland is the producer of Kerto, which is a LVL product.

### 2.2.1 Environmental advantages

The focus has for a long time been to reduce the energy use in the operational phase of a building, building more passive and low energy buildings. More recent studies show that the material choice have relatively greater importance caused by this development [10]. This is illustrated by Figure 2.4. Emissions related to materials can be responsible for almost $50 \%$ of the total energy use.

Figure 2.4: Energy use of a new energy-efficient building [10]

Low density of wood products reduces the transport and assembly costs. It also have a positive effect on the amount of concrete foundation needed. Figure 2.5 shows a simple comparison of the GWP-value, the global warming potential, of different wood products compared with concrete.

Figure 2.5: The emission of $\mathrm{CO}_{2}$ in the production phase of different materials [39]

### 2.3 Structural system

Wood has not traditionally been used in the structural system of high-rise buildings, but for the last couple of decades there has been an increasing interest and development on the matter. Because wood is a flexible and light material, there are some dynamic challenges when building higher structures. Solving these challenges, a structural system based on wood can mean both economic and environmental advantages over systems in concrete and steel.

Figure 2.6: Examples of high-rise timber structures

Figure 2.6a shows Treet in Bergen, which is an example of a new way to build high-rise buildings using wood. Where the horizontal stabilisation is provided by glulam trusses, inspired by the method used for timber bridges. The same truss structure will be used in Mjøstårnet in Brumunddalen, finished in 2018. It will with its 66 metres become the highest timber building in the world [8]. Another structural system is based on CLT elements, and is used in many of the new tall timber buildings in Norway. Figure 2.6b shows Moholt $50 \mid 50$, which is the biggest element structure of CLT in Europe, located in Trondheim and finished in 2016 [17]. The CLT elements act both as load bearing and horizontal stabilisers. The wall elements become part of the support system, restricting the floor spans to 5-6 metres. Another approach is Trä8. This is a building system developed by Moelven, with continuous columns, beams, prefabricated composite walls and prefabricated floors [42].

The system investigated in this work is based on glulam columns and beams, and cassette floor solutions. The columns are continuous and the the column-beam-connections have a high rotational stiffness. This will be the horizontal stabilisation in one direction. The other direction will be stabilised with shear walls or a stiff core. Figure 2.7 is an early proposal for a possible lay-out [14].

Figure 2.7: Structural system of moment resisting frames

### 2.3.1 Moment resisting frames, MRF

Moment resisting frames are the basis for the structural system in this work. They allow bigger spans and open architecture, provided that the connections have the necessary strength and stiffness. This will also enhance lateral building stiffness and improve comfort properties of floors [13].

This was the basis for the preliminary analysis done by Malo and Stamatopoulos (2016). Their analysis show that the minimum rotational stiffness required for a moment resisting connection is about $10000 \mathrm{kNm} / \mathrm{rad}$ for a 10 storey building [13]. Figure 2.8a show the case study; a 30 m high, 10 storey building, with floor spans of 8,3 , and 8 m . Spacing the frames 2.4 m apart and having $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ cross sections of strength class GL30c.

Through experimental testing, Lied and Nordal achieved connections with rotational stiffness of 5000 to $10000 \mathrm{kNm} / \mathrm{rad}$ and moment capacity between 80 to 130 kNm in their master thesis. This is for a single cross-section beam and column GL30c, both with dimensions $140 \mathrm{~mm} \times 450 \mathrm{~mm}$. In the case of a doubled cross section, the stiffness would be doubled and the required rotational stiffness is possible to achieve [20]. Figure 2.8 b shows a prototype of the connection. Threaded rods with a diameter of 2025 mm are screwed into the glulam beam and column and connected using a steel ring. Investigation of this solution concluded that the assembly was feasible, but the design is still in development.

## Slabs

The structural system should have slab solutions that can span up to 10 metres, without increased storey heights. The elements should be prefabricated for easy mounting on site. The slabs will probably be a cassette type design. Compared to CLT floor elements, these type of floors have higher stiffness, making it possible for longer spans. The slabs

Figure 2.8: Moment resisting frames
are expected to contribute to the global stability and load carrying of the building together with the moment resisting frames.

Figure 2.9 show some examples of solutions, where a variation of the cassette design (upper right) is the most likely solution. In this thesis there will be no further investigation of slab solutions and their properties, but a design proposal from WoodSol will be used as base.

Figure 2.9: Different design and materials of slab solutions [39]. CLT-plates, rib-slabs and a cassette solution

### 2.4 Loads

This section gives an overview of relevant loads and load combinations. The load actions are determined using NS-EN 1991 [24] and combined accordring to NS-EN 1990 [23] .

### 2.4.1 Dead load

The dead load of the buildings is dependent upon the material choices for the structural system. Glulam for beams and columns, and CLT for shear walls. Their densities are listed in Table 2.3. No load from permanent technical installations, facades, balconies or inner walls are included. For the slabs the dead load is based on the work done by Bjørge and Kristoffersen for the WoodSol project [4]. They used dead load of $200 \mathrm{~kg} / \mathrm{m}^{2}$. The same is done in this thesis. The effect of higher mass is evaluated in the Discussion, Chapter 5.

Table 2.3: Density of wood materials

| Material | $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | Source |
| :--- | :---: | :--- |
| GLT (glue laminated timber) | 430 | Moelven [19] |
| CLT (cross laminted timber) | 400 | Martinsons [35] |
| LVL (laminated veneer lumber) | 480 | Kerto, Moelven [18] |

### 2.4.2 Live load

The live load is decided by the building category, which describes the intended use. The buildings in this thesis may be used for offices, as well as apartments, giving a distributed live load of $q_{k}=3 \mathrm{kN} / \mathrm{m}^{2}$. This load is used on all floors except the roof, according to Eurocode [23]. The relevant categories and associated loads are listed in Appendix A.2.

### 2.4.3 Snow load

The roof has a distributed snow load. The load is dependent on the geographical location, typology of the building and its roof slopes. The snow load used is valid for buildings with flat roofs in the biggest cities in Norway, $s_{k}=2.8 \mathrm{kN} / \mathrm{m}^{2}$. The equations for calculating snow load are found in Appendix A.3.

### 2.4.4 Wind load

The wind load is depended upon the buildings geographical location and geometry. The wind loads are calculated in accordance to NS-EN 1991-1-4 [26], which treats the wind as a static load. This method is a simplification, but gives reasonable results for deflection and accelerations and is assumed to be the most feasible way to calculate the wind loads for this work.

Figure 2.10: Structural dimensions and reference height [26]
When using the method in NS-EN 1991-1-4 the geometry needs to be simplified to a box-like structure. Figure 2.10 shows the approved geometry of the building that wind loads should be calculated for. For complex geometries the method in Eurocode is not satisfactory.

To find the resulting wind force on buildings, the external and internal forces are added, Equation (2.1). Friction forces are neglected. The buildings are only considered for an urban environment, terrain category IV. A building in more open areas would have higher wind loads and the horizontal displacements would increase. The formulas for the complete calculation of the wind loads are found in Appendix A.4.

External and internal forces:

$$
\begin{align*}
& F_{w, e}=c_{s} c_{d} \sum_{\text {surfaces }} w_{e} \cdot A_{\text {ref }}  \tag{2.1a}\\
& F_{w, i}=\sum_{\text {surfaces }} w_{i} \cdot A_{\text {ref }} \tag{2.1b}
\end{align*}
$$

where

$$
\begin{array}{ll}
c_{s} c_{d} & \text { is the structural factor, formulas for calculation in Appendix A.4.2 } \\
w_{e} & \text { is the wind pressure on external surface at reference height } z_{e}
\end{array}
$$

| $w_{i}$ | is the wind pressure on internal surface at reference height $z_{i}$ |
| :--- | :--- |
| $A_{r e f}$ | is the reference area |

External and internal wind pressure:

$$
\begin{align*}
w_{e} & =q_{p}\left(z_{e}\right) \cdot c_{p e}  \tag{2.2a}\\
w_{i} & =q_{p}\left(z_{i}\right) \cdot c_{p i} \tag{2.2b}
\end{align*}
$$

where
$q_{p}(z) \quad$ is the peak velocity pressure at reference height, formulas for calculation in Appendix A.4.1. $q_{p}(z)$ is calculated for Trondheim, where the reference wind speed is $26 \mathrm{~m} / \mathrm{s}$.
$c_{p} \quad$ is the pressure coefficient, formulas for calculation in Appendix A.4.3

(a) From Eurocode

(b) Simplified

Figure 2.11: Wind pressure over the height, $q_{p}(z)$

(a) Wind zones as in Eurocode

(b) Simplified

Figure 2.12: Wind zones on walls

The velocity profile vary both vertically and horizontally, illustrated by Figure 2.11 and 2.12. A conservative simplification in this work, is not to vary the pressure profile over the height of the building and only use $q_{p}(h)$. Another simplification is that the walls parallel to the wind direction only use the velocity pressure from the zone with the highest pressures, zone A. This leaves to calculate wind for zone A, D and E at height $h$. The wind loads are then applied as line loads on the external columns of the building, see Figure 2.13.

Figure 2.13: Distribution of wind load in Abagus

The roof is also sectioned into different wind zones, but the effect from the wind load on the roof is has little effect on the horizontal displacement, and is thus neglected. Exemplified in Appendix A.4. The wind loads used in the different models are listed in Appendix A.4.4.

### 2.4.5 Limit states

## Ultimate limit state, ULS

The fire load is checked in accordance with the ULS requirements for design of construction parts. The capacity is determined with the least favorable combination of the following load combinations:

$$
\begin{gather*}
\sum \gamma_{G, j} \cdot G_{k, j}+\gamma_{Q, 1} \psi_{0,1} \cdot Q_{k, 1}+\sum \gamma_{Q, i} \psi_{0 i} \cdot Q_{k, i}  \tag{2.3a}\\
\sum \xi \cdot \gamma_{G, j} \cdot G_{k, j}+\gamma_{Q, 1} \cdot Q_{k, 1}+\sum \gamma_{Q, i} \psi_{0, i} \cdot Q_{k, i} \tag{2.3b}
\end{gather*}
$$

The load factors are defined in Appendix A.1. For this work, Equation (2.3a) is used: $1.35 \cdot G+1.05 \cdot Q+1.05 \cdot S+0.9 \cdot W$, where
$G \quad$ is the permanent load
$Q \quad$ is the live load
$S \quad$ is the snow load
$W \quad$ is the wind load

## Serviceability limit state, SLS

For multi-storey timber buildings, serviceability requirements, as deformation and comfort properties, may govern the design.

$$
\begin{equation*}
\sum G_{k, j}+Q_{k, 1}+\sum \gamma_{Q i} \psi_{0, i} Q_{k, i} \tag{2.4}
\end{equation*}
$$

In this work the characteristic load combination, Equation (2.4), is used for serviceability calculation: $G+W+0.7 \cdot Q+0.7 \cdot S$, with wind being the dominant variable load. 0.7 is used as a factor because the live load and the snow load will have a positive effect on the horizontal deflections.

There is no maximum limit for horizontal displacement stated in the Eurocodes. Each project defines their own limit. For WoodSol the limit is $H / 500$, where $H$ is the total height of the building. The maximum peak acceleration at the top floor of the building should be within the guidelines of ISO 10137 [9], see Section 2.5.1. For the calculation
of the acceleration, $30 \%$ of the live load can be added as mass in the modal analysis. This comes from the assumption that some of the live load is quasi-permanent. The quasi-permanent factor of live load is, $\psi_{2}=0.3$ for office areas and residential buildings [23]. The effect of this is investigated in the thesis, but not included in all calculations.

### 2.5 Acceleration

Structural response due to wind loading is a complex phenomenon. Partially because of the complexity of the wind itself, but also because of how the flow pattern is distributed around the building. Especially vibrations of high-rise buildings have to be given careful attention, and it is important to be aware of the weaknesses and limitations of the chosen method. The along-wind response of a building can be divided into a mean component and a fluctuating component. The mean component is a result of the mean wind speed, and can be dealt with in a static manner. The fluctuating component is wind-speed variations from the mean, often referred to as turbulence. This is a random process which is dependant upon the shape of the building, surrounding terrain and wind profile, among other things. The aerodynamic effects due to turbulence results in vibrations of the structure in translation and torsional modes. The level of vibrations is measured by the accelerations of the top floor. The two most common methods to find accelerations are listed below.

1. Wind tunnel testing

## 2. Gust factor approach

Wind tunnel testing is suitable for large, irregular buildings or very flexible buildings where the aerodynamic effects becomes greater. In wind tunnel testing, the test model is equipped with sensors that measures accelerations.

The gust factor approach is based on the separation of wind loads into mean and fluctuating components [16]. The fluctuating component is taken into account by the intensity of turbulence and dynamic amplification. NS-EN 1991-1-4 [26] uses the gust factor approach to calculate the accelerations of the top floor as it includes the turbulence effects in resonance with the considered vibration mode. When the gust factor approach is used to calculate the acceleration, one can predict the dynamic response of the building with reasonable accuracy [16]. Even though the method in NS-EN 1991-1-4 is considered satisfactory to predict accelerations, is it important to know the limitations and assumptions which the method is built upon. For instance does the method require a pure translation vibration mode in the wind direction. It is recommended to perform a wind tunnel test if the fundamental vibration mode is a torsional mode, or a translation mode in the cross-wind direction. The same goes for buildings with irregular shape. The approved shapes are shown in Figure 2.14.

Figure 2.14: Approved shapes for calculation of acceleration [26]

### 2.5.1 Acceleration criteria

Today, there is no internationally agreed comfort criteria when it comes to vibrations. Each project can define its own comfort criteria and limits for deflection in the serviceability limit state. The main reason for this is that the perception of acceleration differ from person to person, as some people are more sensitive to vibrations than others. However, the evaluation curves for wind-induced vibrations in ISO 10137 [9] has been frequently used, see Figure 2.15. The curve shows that the comfort criteria varies with the fundamental frequency of the building, and shows the strictest criteria for a frequency range between 1 and 2 Hz , where the peak acceleration should not exceed 0.04 $\mathrm{m} / \mathrm{s}^{2}$.

Figure 2.15: Evaluation curves for wind-induced vibrations [9]
where
$A \quad$ is the peak acceleration
$f_{0} \quad$ is the natural frequency of the building
1 is the curve for offices
2 is the curve for residences

Numerous researchers have tried to predict motion threshold levels for humans due to vibrations. Boggs [5] found that the lower limit for perception of acceleration is 0.02 $\mathrm{m} / \mathrm{s}^{2}$, but only $2 \%$ of the population are able to feel that, while a less strict limit of 0.05 $\mathrm{m} / \mathrm{s}^{2}$ can be felt by half of the population. Mendis, Ngo, Haritos, Hira, Samali and Cheung [16] suggests different perception levels, summarised i Table 2.4. Depending of the usage of the building and the project specific limits, one can define a comfort criteria for acceleration which is either higher or lower than the ISO-curve, if Boggs' or Mendis' et. al. criteria is used.

Table 2.4: Human perception levels [16]

| Acceleration $\left[\mathrm{m} / \mathrm{s}^{2}\right]$ | Effect |
| :---: | :--- |
| $<0.05$ | Humans cannot perceive motion |
| $0.05-0.10$ | Sensitive people can perceive motion |
|  | and hanging objects may move slightly |
| $0.10-0.25$ | Majority of people will perceive motion |
| $0.25-0.40$ | Desk work becomes difficult |
| $>0.85$ | Objects begin to fall and people may be injured |

All of the above acceleration limits are given as peak acceleration, rather than root-mean-square (RMS) acceleration. The difference between the two is that the peak acceleration neglect the smaller amplitudes of vibrations and focus on the peak value over a given period of time. RMS acceleration focus on some average effects over the same time period. As a consequence of this, RMS gives a lower limit than the peak acceleration. For a sinusoidal wave, the RMS is a factor $\sqrt{2}$ lower than the peak value. Today, the peak acceleration is preferred, even though one can argue to use the mean value of the RMS and the peak value [5]. The peak acceleration is used in this thesis.

### 2.5.2 Acceleration calculation in accordance to NS-EN 1991-1-4

The acceleration of the building can be calculated using Equations (2.5) and (2.6).

$$
\begin{equation*}
a=\sigma_{a, x} \cdot k_{p} \tag{2.5}
\end{equation*}
$$

where
$\sigma_{a, x} \quad$ is the standard deviation of the wind induced acceleration
$k_{p} \quad$ is the peak velocity factor

$$
\begin{equation*}
\sigma_{a, x}(z)=\frac{c_{f} \cdot \rho \cdot b \cdot I_{\nu}\left(z_{s}\right) \cdot v_{m}\left(z_{s}\right)^{2}}{m_{e}} \cdot R \cdot K_{x} \cdot \phi_{1, x}(z) \tag{2.6}
\end{equation*}
$$

where
$c_{f} \quad$ is the force coefficient
$\rho \quad$ is the air density, $\rho=1.25 \mathrm{~kg} / \mathrm{m}^{3}$
$b \quad$ is the width of the structure
$I_{\nu}\left(z_{s}\right) \quad$ is the turbulence intensity
$v_{m}\left(z_{s}\right)$ is the mean wind velocity, calculated with a return period of 2 years
$z_{s} \quad$ is the reference height, $z_{s}=0.6 \cdot h \geq z_{\text {min }}$, see Figure 2.14
$R \quad$ is the square root of the resonance response
$K_{x} \quad$ is the non-dimensional coefficient
$m_{e} \quad$ is the along wind fundamental equivalent mass
$\Phi_{1, x}(z) \quad$ is the fundamental along wind modal shape
The equivalent mass, $m_{e}$, can be calculated in two different ways. Either with the exact integral i Equation (2.7), or in a simplified manner based on properties of the upper third of the building, shown in Equation (2.8).

$$
\begin{equation*}
m_{e}=\frac{\int_{0}^{l} m(s) \cdot \Phi^{2}(s) \mathrm{d} s}{\int_{0}^{l} \Phi^{2}(s) \mathrm{d} s} \tag{2.7}
\end{equation*}
$$

where
$m(s) \quad$ is the mass per unit length
$\Phi(s) \quad$ is the considered mode shape

$$
\begin{equation*}
m_{e}=\frac{m_{3}}{h_{3}} \tag{2.8}
\end{equation*}
$$

where
$m_{3} \quad$ is the average value of the mass over the upper third of the building $h_{3} \quad$ is the height of the upper third of the building The rest of the variables used to calculate the acceleration are defined in Appendix B.

### 2.6 Structural fire design

Wood is a combustible material, and between 1907 and 1997 multi-storey timber buildings were not allowed in Norway, due to the risk of city fires [11]. Improved knowledge of fire design in timber buildings and development in technical measures like sprinklers and smoke detection systems opened for a wider use of wood as a construction material.

Fire safety is depended on the structural system. It is important that the occupants of the building can be rescued. To help this, the building should be designed in a way reducing spread of fire and smoke, and ensuring that the load-bearing structure parts resist fire for a minimum duration of time. This section summarize the relevant fire safety requirements for designing the structural system for high-rise timber buildings. The fire design method for construction parts in wood can be found in NS-EN 1995-1-2 [28], and the Norwegian fire regulations are from the Byggteknisk forskrift, TEK10.

### 2.6.1 Requirements

The fire resistance of a building component is classified as the load carrying capacity (R), integrity ( E ) and insulation (I), followed by the resistance time required in minutes. How materials react to fire are described by their inflammability (A-F), the smoke development (sl-3) and admittance of burning droplets (d0-2). A product used as fire protective cladding is classified by $K_{1}(10 \mathrm{~min})$ or $K_{2}(10,30$ or 60 min$)$ [21].

The fire safety requirements of a building are governed by the risk and fire class. A buildings risk class describes the use of the building, and the fire class is a measure of how critical the consequences would be in a case of fire, with respect to human lives and interests of the society. Buildings over five storeys, with a risk class between two and five (includes residences, offices and stores), are fire class 3 [38, §11-2 and §11-3]. This risk class will apply to all buildings investigated in this thesis.

Table 2.5: Fire protection requirements [38, §11-4]

| Load carrying building component | Fire class 3 |
| :--- | :--- |
| Main load carrying system | R90 A2-s1, d0 |
| Secondary load carrying system (floor separators, roof) | R60 A2-s1, d0 |
| Stairwell | R30 A2-s1, d0 |

Table 2.5 list the preaccepted requirements in TEK 10. For buildings lower than eight storeys the floor separators can have fire resistance of R60 A2-s1, d0, even though they
are a part of the global stabilisation of the building [38, §11-4(4)]. For buildings over eight storeys, an additional staircase is required [38, §11-13], as well as elevated pressure in escape stairways. The maximum distance from the exit of a fire compartment to the staircase is 15 metres [38, §11-14]. The additional costs for building higher than eight storeys makes it more reasonable to build e.g. 12 instead of nine storeys in total, if the "eight storey limit" should be exceeded in the first place ${ }^{4}$.

For buildings in risk class four or higher, an automatic fire extinguishing system is required, and is satisfied by e.g. a sprinkling system [38, §11-12]. In addition, a building should be sectioned into fire compartments that can help delay the spread and contribute to safe escape and rescue. A typical fire compartment would be one apartment. Each compartment should have the resistance of EI60, A2-s1, d0 [38, §11-8]. That means no exposed wood. To allow exposed wood surfaces, the building needs to be considered as a whole, and the fire energy from wood needs to be accounted for. Type of surfaces is not considered any further, but needs to be considered in a complete design process.

### 2.6.2 Fire design

To address the performance of the structural system the reduced cross section method is used. The main load carrying system are the slabs, the shear walls, the beams and columns. This assignment only look at the columns near the foundations. The performance is satisfied when the load-bearing function of the columns is maintained after 90 minutes of fire exposure.

Protective cladding, like fire gypsum, will delay the charring of the columns, but this is not considered in this assignment. All surfaces exposed to fire will char. The char will act insulating, maintaining the temperature on the underlying wood surface. The core of the wood maintains its ability to carry load. The cross section is illustrated by Figure 2.16.

Figure 2.16: Reduced cross section [28]. 1 - initial surface, 2 - residual cross section, 3 - effective cross section

[^3]The remaining effective cross section is decided by the formulas in NS-EN 1995-1-2 [28]:

$$
\begin{align*}
d_{e f} & =d_{\text {char }, n}+k_{0} d_{0}  \tag{2.9a}\\
d_{\text {char }, n} & =\beta_{n} \cdot t \tag{2.9b}
\end{align*}
$$

where
$d_{\text {char }, n} \quad$ is the charring rate for glulam $\beta_{n}=0.7 \mathrm{~mm} / \mathrm{min}$
$d_{0} \quad d_{0}=7 \mathrm{~mm}$
$k_{0} \quad k_{0}=1$ when $t \geq 20$ minutes
For $t=90$ minutes, $d_{e f}=70 \mathrm{~mm}$. This needs to be withdrawn from all sides exposed to fire of the initial cross section. The remaining cross section have to carry $60 \%$ of the design load of the building [28]. Formulas for calculating the capacity of the cross section is given in Appendix C. Note that with one layer of fire gypsum (class $K_{1}$ ), $d_{e f}$ would be reduces to 63 mm .

## Chapter 3

## Modelling and Analysis

The different layouts of the structural system have been modelled in the finite element program Abaqus. The goal of the study is to develop an understanding of the global stability in the serviceability limit state of tall timber buildings built with moment resisting frames. Thus, the modelling has been simplified to only account for what is essential regarding load bearing and stability. The simplifications, assumptions and considerations made during the modelling are discussed in this chapter, as is the case building and the analysis of the model.

### 3.1 Case building

The main goal for the WoodSol project is to develop industrialised structural solutions based on moment resisting frames having five to 10 storeys open architecture [14]. As the same structural solutions will be used in several different buildings, the solutions should be robust and adaptable for small changes. The models from Section 3.5 vary in numbers of storeys and geometry, but should be built by the same principles on a construction site. Based on this, the modelling will also follow the same principles for all models, meaning all Abaqus-models are assembled with the same parts and after the same guidelines:

- Continuous timber columns in full building height
- Slabs merged with beams making the horizontal areas of the floors
- CLT shear walls
- CLT walls to represent stair and elevator shafts
- Nodal masses to represent extra mass

The buildings vary from four to 12 storeys and have footprints varying from roughly 260 to $830 \mathrm{~m}^{2}$. The slabs span from 3 to 9.6 m , and are not wider than 2.4 m . This means that two neighbouring frames can not be farther apart than 2.4 m if the slab between them is meant to contribute to horizontal stiffening in the frame direction. If the distance is larger, the slabs have to be positioned with their span direction orthogonal to the frame direction, and thus be connected to the frame beams and not the columns. See Figure 3.1 for examples of both span directions.

(a) Slab span direction parallell to frame

i.
(b) Slab span direction orthogonal to frame

Figure 3.1: Span directions of slabs

### 3.2 Modelling in Abaqus

Abaqus is a general purpose finite element analysis program with a wide range of opportunities. By a combination of modelling in $\mathrm{CAE}^{1}$, manipulation through the keyword function and usage of input files, almost anything can be modelled. Abaqus lets the user be in control by giving a wide range of options throughout every step of the modelling process and the possibility to customise input. The program also lets the user run Python scripts, which makes parameter studies easier. Abaqus was chosen on the basis of its wide range of possibilities and customisation options.

## Features and elements

All beams and columns are modelled as wire features and meshed with B31 elements. The B31 element is a Timoshenko element, allowing transverse shear deformation. The

[^4]element can be used in stout, as well as slender beams, it uses lumped mass representation and is linearly integrated [33].

Shear walls and slabs are modelled as shell elements. The slabs are in general meshed with S4R elements. S4R is a general-purpose shell element with four nodes that uses reduced integration with hourglass control to calculate its stiffness contribution. It provides accurate solutions for all loading situations. The shear walls are meshed with S4 elements, which is stiffer than the S4R element because it exhibit shear locking. S4 is used to avoid hourglass modes in the shear walls. In special cases, e.g. corridors, where short slabs results in a slab thickness larger than $1 / 15$ of the slab span, the S8R element is used. This element is a 8 -node doubly curved thick shell with reduced integration. It is recommended for use in regular mesh geometries for thick shell applications [33] [34].

Wire features, with assigned connector sections, are used to represent the connections between columns and slabs and between columns and shafts. Wire features are also used between columns and the ground to model a semi-stiff connection as a parametric study of the boundary condition.

## Model assembly

The steps of the assembly of the models are summarised in Figure 3.3. It starts by setting out column pairs where slabs should be put in between. The shear walls are placed out and merged to columns to give the right continuity. The slabs are placed out as continuous shell features with partition areas to represent the connection between each slab, see Figure 3.2a. The slabs are merged with a layer of beams over each partition line to give the right stiffness and bending shape, see Figure 3.2b. This is done because the shell elements used in the slabs do not have rotational degrees of freedom. For the modelling of moment resisting frames to be successful, it is important that the connection nodes between columns and slabs both have rotational degrees of freedom, making manually assigned rotational stiffness between those parts possible. Each slab is connected to four columns, one in each corner, with connection points between the partition and the slab section. This means that every column connected to two slabs in the model has a doubled cross section. Tie constraints are also used to keep the building continuous, typically between building parts not connected by wires, e.g. building parts with different span direction, see Figure 3.4a. In models containing an elevator shaft, the shaft is put between cut out slabs and surrounded by columns, see Figure 3.4b.

Figure 3.2: Slab modelleling

Figure 3.3: Assembly of models

Figure 3.4: Assembling details

## Connections

The slabs are connected to the columns by wire features, so that translations are constrained and rotations are released in two directions. The third rotation direction has a semi-rigid constraint, with rotational stiffness of $10000 \mathrm{kNm} / \mathrm{rad}$. The direction of this stiffness is such that it reduces rotation between the column and slab beam about the strong axis of the beam section, i.e. rotational stiffness about the z -axis in Figure 3.5.

For shafts, all rotations are released, while translations are constrained.

To check for semi-rigid boundary conditions, there has been used pinned boundary conditions accompanied with assigned rotational stiffness of $10000 \mathrm{kNm} / \mathrm{rad}$ about the ground plane axes.

When modelling a wire connection in Abaqus, it has to be a gap between the two connected nodes. To ease the modelling, this gap is large during the modelling and set shorter during simulations. Figure 3.5 visualises the gap, as well as presenting the result that the model seems to stiffen with the gap decreasing. The influence is small, with a deviation of $2.2 \%$. In the modelling, the gap is set to one, and the influence of change is not investigated further.

Figure 3.5: Connection gaps

## Simplifications

In order to use numerical programming to effectively analyse a multiple storey building, simplifications have to be made. If all details (as connection details, screws, walls, etc.) were to be modelled, both simulations and the modelling process would be very time consuming. The main simplifications made are listed below and discussed in Section 5.2.5.

- Slabs are modelled as shell elements merged with beam elements. The modelling is based on an Abaqus model from the master thesis by Bjørge and Kristoffersen [4].
. Only building parts that contribute to the global stability of the building are included. Facades, inner walls etc. are not modelled.
- Multiple slabs are modelled as one part, making the connection between them simplified as an isotropic section with low strength
- Shear walls merged to columns
- Wind load modelled as uniform line load

### 3.3 Verification of numerical modelling

The complexity of modelling a 3D model in Abaqus makes it hard to keep track of every step during creating a model. To ensure the validity of the computations done in Abaqus, a verification process has been completed.

To do so, hand calculations and fap2D have been used. fap2D is a program for static and dynamic analysis of 2D frame structures developed at NTNU at the Department of structural engineering [30]. fap2D has been used to calculate the responses of simple frames for comparison to Abaqus models, while hand calculations have been used to compare the energy balance between 3D and 2D models.

The following tests have been done to validate the computations done in Abaqus:

- Comparison of 2D models modelled in Abaqus and fap2D
- Comparison of bracing between frames modelled in Abaqus and fap2D
- Conversion from 3D in Abaqus to 2D in fap2D
- Energy balance comparison between models

The comparisons between Abaqus and fap2D models are done using steel as the material. This because steel has isotropic properties, and it is easier to ensuring the same representation in the two programs. Wood, on the other hand, is defined with material properties in three independent directions in Abaqus, but only one direction in fap2D.

### 3.3.1 2D model comparison

To compare results from Abaqus and fap2D, it is important to ensure that the modelling done in the two programs gives the same results for the same model.

This test was done by modelling a 2D frame of five storeys with columns and beams. The columns are encastred to the ground, and the beams are connected to the columns with translations constrained and rotation stiffness of $20000 \mathrm{kNm} / \mathrm{rad}^{2}$. The rotational stiffness reduces the rotation between beam and column, with stiffness about the z -axis in the Abaqus model and about the out-of-plane axis in fap2D. See Figure 3.6 and Table 3.1 for the model representation.

[^5]

Figure 3.6: 2D frame, five storeys

Table 3.1: Model input for 2D comparison models

|  | Abaqus and fap2D |
| :--- | :--- |
| Storey height $[\mathrm{m}]$ | 3 |
| Beam length $[\mathrm{m}]$ | 9 |
| Line load on column $[\mathrm{N} / \mathrm{mm}]$ | 5 |
| Line load on beam $[\mathrm{N} / \mathrm{mm}]$ | 12 |
| Gravity constant $\left[\mathrm{m} / \mathrm{s}^{2}\right]$ | 9.81 |
| Rotational stiffness $[\mathrm{kNm} / \mathrm{rad}]$ | 20000 |
| Boundary condition | encastred |
| Material | steel, see Table 3.2 |

Table 3.2: Steel material properties

|  | $\rho\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | $E[\mathrm{MPa}]$ | $v$ |
| :---: | :---: | :---: | :---: |
| Steel | 7850 | 210000 | 0.3 |

The results from the two models and the deviations between results from fap2D and Abaqus in percent are listed in Table 3.3. It is expected that the differences are minimal as the two models in principle are the same model. As shown in the table, there are some small deviations. These may arise from different round-off in the two programs. The differences in results are very small, leading to the conclusion that the simulation of connections are correct.

Table 3.3: Results from comparison between Abaqus and fap2D

| Output | Abaqus | fap2D | Deviation |
| :--- | ---: | ---: | ---: |
| U1 floor 5 [mm] | 14.9185 | 14.92 | $0.010 \%$ |
| U1 floor 3 [mm] | 8.2262 | 8.23 | $0.047 \%$ |
| U1 floor 1 [mm] | 1.4274 | 1.43 | $0.181 \%$ |
| U2 floor 5 [mm] | 2.8666 | 2.87 | $0.118 \%$ |
| U2 floor 3 [mm] | 2.7138 | 2.72 | $0.228 \%$ |
| U2 floor 1 [mm] | 2.3542 | 2.36 | $0.246 \%$ |

$R F 2 L$ is the reaction force on the left column in the y -direction
$R F 2 R \quad$ is the reaction force on the right column in the y -direction
with directions from Figure 3.6a.

### 3.3.2 Bracing by shear walls

There is done a test validating the modelling of shear walls in Abaqus. An eight storey 2D wall is modelled with shear walls merged to columns in Abaqus. This model is converted to a model with cross bracing of circular beam sections in Abaqus, so that it can easily be checked by a similar model in fap2D. The models are presented in Figure 3.7.

Figure 3.7: Models of bracing

The model in Figure 3.7a is modelled with material properties according to Table 3.4. The model shown in Figure 3.7b, with material properties from Table 3.5 is compared to the this model to make sure the cross bracing model can represent a compact shear wall. These material properties are found by iteration. The results from this comparison are presented in Table 3.6.

Table 3.4: Material properties shear wall model

|  | $\rho$ <br> $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | $E_{1}$ <br> $[\mathrm{MPa}]$ | $E_{2}$ <br> $[\mathrm{MPa}]$ | $E_{3}$ <br> $[\mathrm{MPa}]$ | $v_{12}$ | $v_{13}$ | $v_{23}$ | $G_{12}$ <br> $[\mathrm{MPa}]$ | $G_{13}$ <br> $[\mathrm{MPa}]$ | $G_{23}$ <br> $[\mathrm{MPa}]$ |

| Frame | 450 | 13000 | 300 | 300 | 0.6 | 0.6 | 0.6 | 650 | 650 | 65 |
| Cross beams | 1345.5 | 9000 | 4000 | 4000 | 0.6 | 0.6 | 0.6 | 650 | 650 | 65 |

Table 3.6: Results from Abaqus models 3.7a and 3.7b

| Output | Shear wall | Cross bracing | Deviation |
| :--- | ---: | ---: | ---: |
| U1 top [mm] | 51.98 | 51.28 | $1.347 \%$ |
| Natural frequencies $[\mathrm{Hz}]$ | Shear wall | Cross bracing | Deviation |
| Mode |  |  |  |
| 1 | 4.055 | 4.0862 | $0.769 \%$ |
| 2 | 17.478 | 17.819 | $1.951 \%$ |
| 3 | 37.288 | 37.013 | $-0.738 \%$ |

The results show that the cross bracing model can represent the compact shear wall model in Abaqus.

The cross bracing model is then compared to a similar model in fap2D, and the results are presented in Table 3.7. The material choice is steel, with properties from Table 3.2. The small deviations leads to the conclusion that the simulation of shear walls is correct.

Table 3.7: Results from comparison

| Output | Abaqus | fap2D | Deviation |
| :--- | ---: | ---: | ---: |
| U1 top [mm] | 3.022 | 3.04 | $0.006 \%$ |
| Natural frequencies [Hz] | Abaqus | fap2D | Deviation |
| Mode |  |  |  |
| 1 | 4.920 | 4.897 | $-0.005 \%$ |
| 2 | 23.013 | 22.748 | $0.012 \%$ |
| 3 | 46.671 | 46.581 | $-0.002 \%$ |

### 3.3.3 From 3D to 2D

This comparison is done to make sure that the simulation of a 3D model gives logical values for deformations and reaction forces. It is expected that the results will vary when one dimension is taken away because of effects that happen in 3D and not in 2D, and also simplifications done in the 2D model. Two 3D models from Abaqus have been checked against 2D models from fap2D, one with five storeys and one with two storeys, both six slabs wide. This is done to check for accumulation of errors. Figure 3.8 visualises how the sections from the 3D models are transferred to 2D, where the sections are marked in Figures 3.8c and 3.8d. Model input are shown in Table 3.8.

The results for these simulations are presented in Table 3.9 and 3.10.

Figure 3.8: Overview of models

Table 3.8: Model input for 3D to 2D comparison models

|  | Abaqus | fap2D |
| :--- | :--- | :--- |
| Storey height $[\mathrm{m}]$ | 3 | 3 |
| Slab(beam) length $[\mathrm{m}]$ | 9 | 9 |
| Slab width $[\mathrm{m}]$ | 2.4 | - |
| Slab thickness $[\mathrm{mm}]$ | 450 | - |
| Beam section $(\mathrm{h} \times \mathrm{b})[\mathrm{mm}]$ | - | $450 \times 2400$ |
| Line load on column $[\mathrm{N} / \mathrm{mm}]$ | 5 | 5 |
| Line load on beam $[\mathrm{N} / \mathrm{mm}]$ | - | 12 |
| Pressure on floors $\left[\mathrm{N} / \mathrm{mm}^{2}\right]$ | 0.005 | - |
| Gravity constant $\left[\mathrm{m} / \mathrm{s}^{2}\right]$ | 9.81 | 9.81 |
| Rotational stiffness $[\mathrm{kNm} / \mathrm{rad}]$ | 10000 per connection | 20000 |
| Boundary condition | encastred | encastred |
| Material | steel, see Table 3.2 | steel, see Table 3.2 |

Table 3.9: Results from comparison, two storeys

| Output | Abaqus | fap2D | Deviation |
| :--- | ---: | ---: | ---: |
| U1 floor 2 [mm] | 0.7383 | 0.71 | $-3.833 \%$ |
| U1 floor 1 [mm] | 0.2760 | 0.26 | $-5.790 \%$ |

| 3 | 13.5870 | 12.7113 | $-6.4451 \%$ |

Table 3.10: Results from comparison, five storeys

| Output | Abaqus | fap2D | Deviation |
| :--- | ---: | ---: | ---: |
| U1 floor 5 [mm] | 16.2200 | 14.92 | $-8.015 \%$ |
| U1 floor 3 [mm] | 8.8000 | 8.23 | $-6.477 \%$ |
| U1 floor 1 [mm] | 1.5026 | 1.43 | $-4.828 \%$ |
| U2 floor 5 [mm] | 2.3729 | 2.87 | $20.948 \%$ |
| U2 floor 3 [mm] | 2.2227 | 2.72 | $22.374 \%$ |
| U2 floor 1 [mm] | 1.8683 | 2.36 | $26.318 \%$ |
| RF1L [kN] | 39.271 | 38.22 | $-2.676 \%$ |
| RF1R [kN] | 36.669 | 36.78 | $0.303 \%$ |
| RF2L [kN] | 2298.100 | 2265.34 | $-1.426 \%$ |
| RF2R [kN] | 2352.310 | 2312.06 | $-1.711 \%$ |
| Natural frequencies [Hz] | Abaqus | fap2D | Deviation |
| Mode |  |  |  |
| 1 | 0.5700 | 0.5797 | $1.707 \%$ |
| 2 | 2.7101 | 2.6879 | $-0.819 \%$ |
| 3 | 7.0988 | 6.9807 | $-1.664 \%$ |

where
$U 1 \quad$ is the displacement in the x -direction
$U 2 \quad$ is the negative displacement in the y-direction
$R F 1 L \quad$ is the reaction force on the left column in the x-direction
$R F 1 R \quad$ is the reaction force on the right column in the x -direction
$R F 2 L \quad$ is the reaction force on the left column in the $y$-direction
$R F 2 R \quad$ is the reaction force on the right column in the y-direction
with directions from Figure 3.8a.
The results show that the deviations between the two and five storey models does not seem to accumulate. The deviation in downward deformation is quite high. This might be because of the different force propagation paths from a 3D model versus a 2D model. In the Abaqus models, the slabs are plates, while in fap $2 D$, they are modelled as beams. To convert the Youngs modulus, $E$, to a corresponding value in fap2D the formula for downward deformation in a slab has been used, see Equation (3.1) through (3.3), and the deflection is collected from the point shown in Figure 3.9. To fulfill the require-
ments for Equation (3.1), this model has pinned connections between the top slab and the columns. The point of deflection is chosen because it is the midpoint between the largest and the lowest deflection in the model, as the deflection is higher toward the short ends of the model.

Figure 3.9: Red dot marking where the deflection was collected

$$
\begin{equation*}
w=\frac{5 \cdot q L^{4}}{384 \cdot D} \tag{3.1}
\end{equation*}
$$

with

$$
\begin{equation*}
D=\frac{E t^{3}}{12 \cdot\left(1-v^{2}\right)} \tag{3.2}
\end{equation*}
$$

which gives

$$
\begin{equation*}
E=\frac{60 \cdot q L^{4} \cdot\left(1-v^{2}\right)}{384 \cdot w} \tag{3.3}
\end{equation*}
$$

where
$w \quad$ is the downward deflection of the slab.
$q \quad$ is the pressure load on the slab
$L \quad$ is the span length of the slab
$v \quad$ is the poisson ratio of the material
This gives $\mathrm{E}=227000 \mathrm{MPa}$, which is used in an updated fap2D five storey model to give the new results of Table 3.11. These results are more even, but they deviate from
each other with up to 16.7 \% for the downward deflection in the first floor. The U1 deformations are higher in Abaqus while the U2 deformations are lower. This indicates that the model is less stiff than the fap $2 D$ model in the $x$-direction and more stiff in the $y$-direction. For the purpose of this thesis, the downward deformation of slabs is not relevant, as it is the frequencies, reaction forces and the horizontal deformation which is important to check for acceleration, fire and top deflection requirements. The reaction forces and natural frequencies do not deviate by much, while the deviation of the deflection in $x$-direction is about $10 \%$. These deviations are not considered alarming. It is concluded that the modelling technique is valid, and it is used throughout the modelling process of this thesis.

Table 3.11: Results from comparison, five storey

| Output | Abaqus | fap2D | Deviation |
| :--- | ---: | ---: | ---: |
| U1 floor 5 [mm] | 16.2200 | 14.38 | $-11.344 \%$ |
| U1 floor 3 [mm] | 8.8000 | 7.87 | $-10.568 \%$ |
| U1 floor 1 [mm] | 1.5026 | 1.35 | $-10.153 \%$ |
| U2 floor 5 [mm] | 2.3729 | 2.66 | $12.098 \%$ |
| U2 floor 3 [mm] | 2.2227 | 2.52 | $13.376 \%$ |
| U2 floor 1 [mm] | 1.8683 | 2.18 | $16.684 \%$ |
| RF1L [kN] | 39.271 | 38.44 | $-2.116 \%$ |
| RF1R [kN] | 36.669 | 36.56 | $-0.297 \%$ |
| RF2L [kN] | 2298.100 | 2266.11 | $-1.392 \%$ |
| RF2R [kN] | 2352.310 | 2311.43 | $-1.738 \%$ |
| Natural frequencies [Hz] | Abaqus | fap2D | Deviation |
| Mode |  |  |  |
| 1 | 0.5700 | 0.5908 | $3.655 \%$ |
| 2 | 2.7101 | 2.7730 | $2.321 \%$ |
| 3 | 7.0988 | 7.2341 | $1.906 \%$ |

### 3.3.4 Energy comparison

This test validates the modelling of the connections in Abaqus by comparison of both strain energy in the connection, and total internal energy of the system in Abaqus with hand calculations. The considered model is a simple frame, shown in Figure 3.10. The frame is loaded with a point load of 10 kN in the top left corner.

Simplified, the energy balance can be written as shown Equation (3.4).

Figure 3.10: 2D model in Abaqus

$$
\begin{equation*}
E_{t o t}=E_{\text {int }}+E_{\text {ext }}=\left(E_{b}+E_{\text {col }}+E_{\text {con }}\right)+E_{\text {ext }} \tag{3.4}
\end{equation*}
$$

where
$E_{\text {tot }} \quad$ is the total energy in the system
$E_{\text {int }} \quad$ is the internal energy
$E_{\text {ext }} \quad$ is the external energy
$E_{b} \quad$ is the strain energy from beams
$E_{c o l} \quad$ is the strain energy from columns
$E_{c o n} \quad$ is the strain energy from connections
Strain energy contributions from beams and columns are defined in Equations (3.5), (3.6) and (3.7), for moment, shear force and axial force, respectively. Strain energy from the connections are defined in Equation (3.8).

$$
\begin{align*}
& E_{b / c o l}=\frac{1}{2} \int_{0}^{L} M(x) \frac{M(x)}{E I} d x  \tag{3.5}\\
& E_{b / c o l}=\frac{1}{2} \int_{0}^{L} k_{y} V(x) \frac{V(x)}{G A} d x  \tag{3.6}\\
& E_{b / \text { col }}=\frac{1}{2} \int_{0}^{L} N(x) \frac{N(x)}{E A} d x \tag{3.7}
\end{align*}
$$

$$
\begin{equation*}
E_{c o n}=\frac{1}{2} k_{r o t} \phi^{2} \tag{3.8}
\end{equation*}
$$

where

| $L$ | is the length of the beam/column |
| :--- | :--- |
| $M(x)$ | is the moment distribution for the actual beam/column |
| $V(x)$ | is the shear force distribution for the actual beam/column <br> $N(x)$ |
| is the axial force distribution for the actual beam/column |  |
| $E$ | is the Youngs modulus |
| $I$ | is the shear modulus |
| $A$ | is the moment of inertia |
| $k_{r o t}$ | is the rotational stiffness of the connection, $10000 \mathrm{kNm} / \mathrm{rad}$ |
| $k_{y}$ | is the cross-sectional factor, for rectangular cross section, $k_{y}=1.2$ |
| $\phi$ | is the rotation of each connection |

Table 3.12 shows negligible deviations between Abaqus and hand calculations, which strongly indicates that the physical behavior of the connections are modelled correctly. In addition, since the deviations in displacement are under one percent, as seen in Table 3.3, the validity of the modelling technique is approved.

Table 3.12: Strain energy

| Output | Abaqus <br> $[J]$ | Hand calculation <br> $[J]$ | Deviation |
| :--- | :---: | ---: | :---: |
| $E_{b}$ | - | 20570 | - |
| $E_{\text {col }}$ | - | 18833 | - |
| $E_{\text {con }}$ | 23478 | 23477 | $0.004 \%$ |
| $E_{\text {int }}$ | 62352 | 62880 | $0.84 \%$ |

### 3.3.5 Modelling of Slab

As mentioned in Section 3.2, the modelling of the slabs is a simplification, where the material properties are fictitious. The simplified slab is based on the master thesis by Bjørge and Kristoffersen [4], hereafter called the reference slab. The conversion from the reference slab to a simplified slab was done by comparing single slab elements. The considered slab has a dimension of $9 \mathrm{~m} \times 2.4 \mathrm{~m}$. Figures 3.11 and 3.12 shows the reference slab and the simplified model, respectively.

Figure 3.11: Reference slab

Figure 3.12: Simplified slab

As shown in Table 3.13, the simplified slab is able to represent the natural frequencies of the reference slab. The first mode shape is the first bending mode about the weak axis, the second mode is a torsional mode, the third one is translation in the cross direction, while the fourth mode shape is the second bending mode about the weak axis.

The mode shapes are illustrated in Figure 3.13. All of the modes have less than $10 \%$ deviation from the reference model, which is acceptable. Table 3.14 shows a maximum deviation in deflection of $4.5 \%$, which increase the validity of the simplified model. Even though the simplified slabs give approximately the same resulting frequency and deflection as the reference slab, the total mass is too low compared to the reference slab. This makes it necessary to add extra mass when calculating the accelerations. For a slab of dimension $9 \mathrm{~m} \times 2.4 \mathrm{~m}, 523 \mathrm{~kg}$ has to be added per slab.

Figure 3.13: Mode shapes for the simplified slab

Table 3.13: Comparison of natural frequencies

| Mode | Reference model | Simplified model <br> $[\mathrm{Hz}]$ | Deviation |
| :---: | ---: | ---: | ---: |
|  | 9.2934 | 9.3597 | $0.71 \%$ |
| 1 | 14.4570 | 13.9130 | $3.76 \%$ |
| 2 | 19.6440 | 19.5020 | $0.72 \%$ |
| 3 | 23.3800 | 21.6380 | $7.45 \%$ |
| 4 |  |  |  |

Table 3.14: Comparison of deflection

| Load case | Reference model <br> $[\mathrm{mm}]$ | Simplified model <br> $[\mathrm{mm}]$ | Deviation |
| :--- | ---: | ---: | ---: |
| Evenly distributed | 13.58 | 14.00 | $3.09 \%$ |
| Concentrated (center) | 3.94 | 4.12 | $4.54 \%$ |

### 3.4 Material properties in Abaqus

All wood materials in the simulations are modelled as transversely isotropic with linear elastic behaviour.

Wood is an anisotropic material, but can be approximated to an orthotropic behaviour. A research by Stamatopoulos and Malo [36] show that there is little difference in modelling the material as fully orthotropic and transversely isotropic, giving the material equal proprieties in the radial and tangential direction. Transversely isotropic is considered a good approximation of the material behaviour for this work. Figure 3.14 illustrate models of cylindrical orthotropic, transversely orthotropic, and the particular directions in a datum with three perpendicular axes: longitudinal (L), radial ( R ) and tangential (T).

Figure 3.14: Wood models[12] and the particular material directions[6]

## Glue Laminated Timber

Table 3.15 list the material properties for glulam used in the analysis. The density and modules of elasticity are from the manufacturer, Moelven [19] and represent quality GL30C. The remaining values are from the study by Stamatopoulos and Malo [36], which based their Poisson ratios on Dahl's study on mechanical properties of Norway spruce [6].

Table 3.15: Material properties GLT

|  | $\begin{gathered} \rho \\ {\left[\mathrm{kg} / \mathrm{m}^{3}\right]} \end{gathered}$ | $\begin{gathered} E_{1} \\ {[\mathrm{MPa}]} \end{gathered}$ | $\begin{gathered} E_{2} \\ {[\mathrm{MPa}]} \end{gathered}$ | $\begin{gathered} E_{3} \\ {[\mathrm{MPa}]} \end{gathered}$ | $v_{12}$ | $v_{13}$ | $v_{23}$ | $G_{12}$ <br> [MPa] | $\begin{gathered} G_{13} \\ {[\mathrm{MPa}]} \end{gathered}$ | $\begin{gathered} G_{23} \\ {[\mathrm{MPa}]} \end{gathered}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| GL30C | 430 | 13000 | 300 | 300 | 0.6 | 0.6 | 0.6 | 650 | 650 | 65 |

## Cross Laminated Timber

CLT is represented as a composite cross section, modelled in layers of quality C14 and C24. The material stiffness and density are from NS-EN 338 [29] and the manufacturer,

Martinsons [35]. The Poisson ratios are from Dahl [6]. Table 3.16 list the material properties for CLT used in the analysis.

Table 3.16: Material properties CLT

|  | $\rho$ <br> $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | $E_{1}$ <br> $[\mathrm{MPa}]$ | $E_{2}$ <br> $[\mathrm{MPa}]$ | $E_{3}$ <br> $[\mathrm{MPa}]$ | $v_{12}$ | $v_{13}$ | $v_{23}$ | $G_{12}$ <br> $[\mathrm{MPa}]$ | $G_{13}$ <br> $[\mathrm{MPa}]$ | $G_{23}$ <br> $[\mathrm{MPa}]$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathbf{C 1 4}$ | 350 | 7000 | 230 | 230 | 0.48 | 0.42 | 0.50 | 440 | 440 | 50 |
| C24 | 420 | 11000 | 370 | 370 | 0.48 | 0.42 | 0.50 | 690 | 690 | 50 |

The thickness of the plies and the layout are inspired by the elements produced by Martinsons [15]. C24 is used in the load carrying direction and C14 in the other. Table 3.17 lists type of material, thickness and orientation of a three ply CLT element. CLT is used in both the modelling of shear walls and shafts.

Table 3.17: Stacking direction of the CLT elements

| Ply | Material | Thickness | Orientation |
| :---: | :---: | :---: | :---: |
| 1 | C24 | 30 mm | $0^{\circ}$ |
| 2 | C 14 | 30 mm | $90^{\circ}$ |
| 3 | C 24 | 30 mm | $0^{\circ}$ |

## Slabs

The modelling of the slabs is described in Section 3.3.5 and the material properties are presented in Table 3.18.

Table 3.18: Material properties of the slabs

|  | $\rho$ <br> $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | $E_{1}$ <br> $[\mathrm{MPa}]$ | $E_{2}$ <br> $[\mathrm{MPa}]$ | $E_{3}$ <br> $[\mathrm{MPa}]$ | $v_{12}$ | $v_{13}$ | $v_{23}$ | $G_{12}$ <br> $[\mathrm{MPa}]$ | $G_{13}$ <br> $[\mathrm{MPa}]$ | $G_{23}$ <br> $[\mathrm{MPa}]$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Slab | 450 | 15000 | 300 | 265 | 0.6 | 0.6 | 0.8 | 175 | 150 | 385 |

## Partition

The slabs are connected with each other. This connection is in the global analysis represented by a partition that has a low stiffness compared to the slabs. The material of the partition is isotropic, and presented in Table 3.19. See Appendix D for more.

Table 3.19: Material properties of the partition in slabs

|  | $\rho$ <br> $\left[\mathrm{kg} / \mathrm{m}^{3}\right]$ | $E$ <br> $[\mathrm{MPa}]$ | $v$ |
| :---: | :---: | :---: | :---: |
| Partition | 430 | 30 | 0.3 |

### 3.5 Models

This section gives a brief presentation of the different geometries of the analysed models. The models investigated can be divided into two main designs, which have been modified further in a parametric study. The first main design is a building containing two larger open areas separated by a corridor, hereafter called Room Corridor Room, RCR for short. The second main design is a building with a T-section shape, containing two blocks in the flange direction, separated by a third block spanning in the orthogonal direction, the web. This design is hereafter called the T-design. In each of the main designs, there is a base model. This model is used as a reference to learn what affects the building the most with respect to a parametric study. The main models are modelled without a shaft contributing to stability. This is based on the goal of robustness, and to investigate if the requirements can be reached without being dependent on a shaft. The geometric changes concern

- number of storeys
- number of slabs
- shear wall layout
- the presence of a shaft connected to the structural system

The main model in each design and its variations can be found in Section 3.5.1 and 3.5.2.

### 3.5.1 Room Corridor Room, RCR

## Main model

The main model is eight storeys high and six slabs wide, and is presented in Figure 3.15. The number of storeys are chosen based on the WoodSol project guidelines and on stricter fire regulations for buildings higher than eight storeys. The number of slabs were chosen to set a basis for comparison. The input for this model is summarised in Table 3.20, which also is the input for all modifications labelled Base for the RCR design.

Table 3.20: Main model and base input

| Property |  | Values |
| :--- | :--- | :--- |
| Dimenssion of cross sections | mid frames | $280 \mathrm{~mm} \times 450 \mathrm{~mm}$ |
|  | end frames | $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ |
| beams | $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ |  |
| Dimenssions of slabs | room | $9.15 \mathrm{~m} \times 2.40 \mathrm{~m}$ |
|  | corridor | $3.00 \mathrm{~m} \times 2.4 \mathrm{~mm}$ |
| Thickness of slabs |  | 350 mm |
| Thickness of shear walls |  | 90 m |
| Heigth of storeys | 3 m |  |
| Spacing of frames | 2.4 m |  |
| Rotational stiffness connections |  | $10000 \mathrm{kNm} / \mathrm{rad}$ |
| Boundary condition | encastred |  |
| Material properties | see Section 3.4 |  |

Figure 3.15: Main model of design RCR. Table 3.20 for input

## Variations of storeys

By adding storeys, the total mass of a structure will rise, while the stiffness will be reduced as the columns length increases. The impact of influence on the natural frequencies of the structure is investigated by simulating models with varying number of storeys. The variations are shown in Figure 3.16.

Figure 3.16: Variations in number of storeys

## Variation of slabs

Two models with added slabs in the direction orthogonal to the frames are shown in Figure 3.17a and 3.17b. These models are made to investigate how the results are affected by changing the slenderness of the building, and also the impact of adding more moment resisting frames. Figure 3.17c shows a model without the corridor and one of the "room"-blocks. The evaluation of this model will tell how adding or removing frames in their span direction affects the response.

(c) One open section isolated, n8d12-room

Figure 3.17: Variation of slabs

## Shaft added

Every building with more than three storeys must have an elevator, as well as a stairway [38]. The influence of a wooden shaft as a part of the structural system, is investigated through the model shown in Figure 3.18. The shaft in this model is modelled using three ply CLT.

Figure 3.18: Wooden shaft added, n8-shaft

## Slab and shear walls added

Figure 3.19 shows a model with four additional shear walls added, two in each direction. A slab has also been added to maintain symmetry. The influence of extra shear walls is investigated using this model.

Figure 3.19: Seven slabs wide with extra shear walls, n8d7-shear

## Special customisations

In some cases, a high first floor is wanted for e.g. a lobby or an reception area. Figure 3.20a and 3.20b show seven storey buildings with the same height as the main model. These models are investigated to learn the consequences of removing a lower floor from the structural system, checking for the contributions from slabs, beams and column height.

Figure 3.20c shows a four storey model which is placed on top of a virtual existing concrete building. The results from this model are used in a short introductory discussion on the application of light timber structures used to expand existing buildings.

Figure 3.20: Special customisations of RCR

### 3.5.2 The T-design

## Main model

The main model have five slabs in each of the blocks making the flange, and nine slabs making the web, see Figure 3.21. As for the RCR design, this model also has eight storeys. This design is more complicated than the RCR design, due to lack of symmetry about one plane axis, this is discussed in more detail in the Discussion chapter, 5. The input for this model is summarised in Table 3.21, which also gives the input for all modifications labelled Base for the T-design.

Table 3.21: Main model and base input

| Property | Values |  |
| :--- | :--- | :--- |
| Dimenssion of cross sections | mid frames | $280 \mathrm{~mm} \times 450 \mathrm{~mm}$ |
|  | end frames | $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ |
|  | beams | $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ |
| Dimenssions of slabs |  | $9.6 \mathrm{~m} \times 2.4 \mathrm{~m}$ |
| Thickness of slabs | 350 mm |  |
| Thickness of shear walls |  | 90 mm |
| Heigth of storeys | 3 m |  |
| Spacing of frames | 2.4 m |  |
| Rotational stiffness connections |  | $10000 \mathrm{kNm} / \mathrm{rad}$ |
| Boundary condition | encastred |  |
| Material properties | see Section 3.4 |  |

Figure 3.21: Main design of the T-model. Table 3.21 for input

## Slabs added in the web

The number of slabs in the web is increased to 15 , see Figure 3.22. This will alter the footprint of the building, and the influence on results are investigated.

Figure 3.22: Six slabs added to the web, n8-long-web

## Shaft added

The influence of a wooden shaft is investigated through the models shown in Figure 3.23. The shaft in this model is modelled using five ply CLT. The shaft is added where the web meets the flange because this is a plausible position for an entrance. It may also increase the stiffness of the web, influencing the torsional eigenmodes of the design.

A model with a shaft added as well as a shear wall on the opposite side of the web has been made, see Figure 3.23b. The results for this model are used to discuss the extra contribution to the models stiffness, when a shaft is already added.

Figure 3.23: T-design with wooden shaft

## Six storey models

A six storey variation of the design is shown in Figure 3.24a. Figure 3.24b shows same the model with added shear walls. These models are used to investigate the influence of both lowering the building, and adding shear walls.

Figure 3.25a shows a different shape of the six storey model. In this model, six slabs have been added to the flange, while two slabs have been removed from the web. This is to understand the change in response due to changing the shape toward a more slender building. This configuration is also checked with added shear walls, see Figure 3.25b

### 3.5.3 Summary

Table 3.22 and 3.23 summarises the geometrical differences between the submodels in the RCR design and the T-design, respectively. The geometrical similarities between the submodels have been presented in Table 3.20 and 3.21.

Table 3.22: Variations in RCR design

| Model | Storeys |  | Height | \# of Slabs | Span |  | Extra shear |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| n | H $[\mathrm{m}]$ | d | x-dir $[\mathrm{m}]$ | z-dir $[\mathrm{m}]$ |  |  |  |
| Main | $\mathbf{8}$ | $\mathbf{2 4}$ | $\mathbf{6}$ | $\mathbf{1 4 . 4}$ | $\mathbf{2 1 . 3}$ | no | no |
| n6d6 | 6 | 18 | 6 | 14.4 | 21.3 | no | no |
| n7d6 | 7 | 21 | 6 | 14.4 | 21.3 | no | no |
| n12d6 | 12 | 36 | 6 | 14.4 | 21.3 | no | no |
| n8d10 | 8 | 24 | 10 | 24.0 | 21.3 | no | no |

### 3.6 Analysis

## Approach

For each model and customisation, the same formula is followed. First, a modal analysis is done to find the models dynamic properties. This is done by executing a linear perturbation step in Abaqus with Lanczos as the iteration method. The outputs from this step are the systems natural frequencies and their associated eigenmodes. The natural frequencies and masses of the models are used to calculate the acceleration and the structural factor $c_{s} c_{d}$ as explained in Appendix A.4. $c_{s} c_{d}$ is then used to calculate the static wind loads in both the x - and the z -direction, which are included in load combinations applied to the model in a static linear perturbation step. Both ULS and SLS load combinations are checked, giving results for evaluating the fire design and the deflections in the top of the building. All simulations are in the linear domain.

The calculated wind loads for each model can be found in Appendix A. 4 together with the formulas for wind load from NS-EN 1991-1-4 [26]. The deflection is only evaluated in the direction of the wind force, while the deflection perpendicular to the wind direction is neglectable in comparison.

## Parametric study

A parametric study is done on the main model of each design. The parameters tested are

- column sections
- shear wall thickness
- rotation stiffness in connections between frames and beams
- different boundary conditions
- added mass in all the floors, or in the top floors of the building

The results from the parametric study for the main models decide what modifications will be done for the other models, aiming for an improvement on the results regarding acceleration, deflection and fire durability. This means that only the most effective modifications are investigated for the other models of each design, as well as combinations of these modifications.

## Fire design

To check for the fire design requirements, the columns are sorted into groups. Columns with the same cross section size and the same sides exposed to a potential fire will fall
into the same group. The maximum reaction forces for each group are used to check if the sections are sufficient to withstand a 90 minute fire.

The design fire load and utilisation of capacity for the most vulnerable cross section are listed in tables throughout Chapter 4. The results are only listed for modifications where the acceleration is at a low level for the given model, or for the modifications where the columns are most affected by strong reaction forces. This way, the most critical modification is checked.

## Remarks on main designs

The T-design has a more complex geometry compared to the RCR design. Where the RCR models are symmetric about both the $x$ and the $z$-axis, the T-design models are only symmetric about the x -axis (with the exceptions of models including a shaft ${ }^{3}$, which are unsymmetrical). This results in torsional eigenmodes. As described in Section 2.5, the formula for calculating accelerations is only valid for translation eigenmodes. The consequence is that only the $x$-direction, where a translation eigenmode can be found, is checked for acceleration for the T-design models. The torsional eigenmode with most mass contribution in z-direction is however used to calculate the $c_{s} c_{d}$ factor to find the wind loads in this direction, as presentet in Appendix A.4. For more comprehensive investigation of accelerations and behavior for the T-design models, wind tunnel testing is recommended.

[^6]
## Chapter 4

## Results

This chapter presents the results from the parametric study done on the different models. The frequencies, acceleration, deflection and reaction forces are evaluated for different modifications of the models, and the most important values are presented. Not all requirements are evaluated for every modification. Evaluation of deflection and fire design are leaved out in some of the simulations as the acceleration is the governing requirement. A summary and discussion of the results are found in Chapter 5.

### 4.1 Design: Room Corridor Room, RCR

This section presents the results from the analyses of the Room Corridor Room design, RCR. The main model is presented thoroughly with results for many modifications. The main model is followed by presentations of the most important results for the variation of number of storeys, number of slabs, additional shafts and shear walls and the special configurations.

### 4.1.1 Main model

## Acceleration

Table 4.1 gives an overview of the different modifications of parameters and the resulting frequencies and accelerations. The deviation from the acceleration of the base model is also included. The base model has the properties represented in Table 3.20. The total and equivalent mass, $m_{e}$, are listed for every modification and used in the

(a) Mode shape 1

(b) Mode shape 2

Figure 4.1: The two first mode shapes of the RCR main model, Base
calculation of the acceleration, see equations in Section 2.5. For the base model the acceleration is $0.080 \mathrm{~m} / \mathrm{s}^{2}$ in the direction of the frames ( x - dir ) and $0.134 \mathrm{~m} / \mathrm{s}^{2}$ in the shear wall direction (z-dir). Figure 4.1 show the mode shapes of the base model for the two first modes. A combination of increasing the cross section of the columns and adding mass in the top two floors will decrease the acceleration to $0.041 \mathrm{~m} / \mathrm{s}^{2}$ in the x -direction and $0.065 \mathrm{~m} / \mathrm{s}^{2}$ in z -direction. The maximum acceleration for a residential building with frequencies between 1 and 2 Hz is $0.04 \mathrm{~m} / \mathrm{s}^{2}$, according to ISO-10137 [9].

Table 4.1: Frequencies and accelerations, RCR main model

|  | Modification | Mass [kg] |  | Frequency [ Hz ] |  | Acceleration [m/ $\mathrm{s}^{2}$ ] |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

[^7]

Figure 4.2: The RCR main model, Base, with an extra shearwall in the corridor

## Deflection

The deflections under the SLS load combination are listed in Table 4.2, together with the deviation from the accepted deflection. The maximum deflection for a 24 m high building is 48 mm . The deflection in U1 is the deflection in the x -direction from wind load in x -direction. U3 is for the z -direction under wind load in z -direction. The different modifications are from Table 4.1.

Table 4.2: Deflection, RCR main model

|  | Modification | Deflection $[\mathrm{mm}]$ |  |  |  |
| :--- | :--- | ---: | ---: | ---: | ---: |
|  |  | U 1 | $\Delta U 1 /_{\text {max }}$ | U 3 | $\Delta U 3 /$ max |
| 1 | Base | $\mathbf{3 8 . 8}$ | $-19 \%$ | $\mathbf{6 1 . 0}$ | $27 \%$ |
| 2 | $t_{\text {shear }}=180 \mathrm{~mm}$ | 38.8 | $-19 \%$ | 52.7 | $10 \%$ |
| 3 | $k_{\text {rot }}=20000 \mathrm{kNm} / \mathrm{rad}$ | 30.1 | $-37 \%$ | 60.7 | $27 \%$ |
| 4 | Cross section $280 \times 900$ | 18.4 | $-62 \%$ | 23.2 | $-52 \%$ |
| 6 | $\rho$ doubled top two floors | 38.9 | $-19 \%$ | 61.0 | $27 \%$ |
| 9 | Combination $4+6$ | 18.4 | $-62 \%$ | 23.2 | $-52 \%$ |
| 12 | BC: $k_{\text {rot }}=10000 \mathrm{kNm} / \mathrm{rad}$ | 45.7 | $-6 \%$ | 61.8 | $29 \%$ |
| 13 | BC: pinned | 56.1 | $17 \%$ | 62.7 | $31 \%$ |

## Fire design

The fire design loads are $60 \%$ of the ULS load combination. Table 4.3 lists the fire loads for the base model. The capacity is evaluated for the worst affected columns. The loads do not necessarily occur on the same column, but are the maximum loads for the col-
umn group ${ }^{4}$. The formulas for calculating the capacity of the cross section are listed in Appendix C. The cross sections are checked for shear, combined bending and tension, combined bending, compression and buckling. The capacity control regarding lateral torsional instability has only been checked for the main models. This is justified by a control of the increased cross sections, showing that lateral torsional instability is prevented, see Appendix C.

For the Room Corridor Room design, the most vulnerable columns are the corner columns and the exterior corridor columns, illustrated in Figure 4.3a. These columns have initial cross sections with dimensions $140 \mathrm{~mm} \times 450 \mathrm{~mm}$. The corner columns are reduced by fire load on two sides, and the exterior columns in the corridor, reduced by fire load on three sides. The utilisation of the capacity is shown in Table 4.4. Figure 4.3b illustrates the axis system used for fire design.

Figure 4.3: Column grouping and axis system

### 4.1.2 Variation of storeys

Table 4.7 presents an overview of the different modifications for the six, seven and 12 storey model. The total and equivalent mass are listed, together with the frequency, acceleration and the deviation of acceleration from the base model.

## Acceleration

(a) Six storeys

(b) Seven storeys

(c) 12 storeys

Figure 4.4: The first mode shape (in x-direction) for the six, seven and 12 storey model

Table 4.7: Frequencies and accelerations, n6d6, n7d6, n12d6

## Deflection

The deflections of the combinations from Table 4.7 are listed in Table 4.8, alongside the deviation from the requirement. For six storeys the requirement is 36 mm , for seven it is 42 mm and for 12 it is 72 mm . The results from the main model (eight storeys) are presented for comparison.

Table 4.8: Deflections, n6d6, n7d6, n12d6

| Modification | Deflection $[\mathrm{mm}]$ |  |  |  |
| :--- | ---: | ---: | ---: | ---: |
|  | U 1 | $\Delta U 1 /_{\max }$ | U 3 | $\Delta U 3 /_{\text {max }}$ |
| Main model (eight storeys) | 38.8 | $-19 \%$ | 61.0 | $27 \%$ |
| Six storeys, n6d6 |  |  |  |  |

| Seven storeys, n7d6 |  |  |  |  |
| Base | 21.9 | $-48 \%$ | 34.0 | $-19 \%$ |
| Combination 3 + 4 | 11.0 | $-74 \%$ | 14.5 | $-65 \%$ |
| 12 storeys, n12d6 |  |  |  |  |
| Base | 126.1 | $75 \%$ | 338.5 | $370 \%$ |
| Combination 2 + 3+4 | 69.4 | $-4 \%$ | 118.2 | $64 \%$ |

## Fire design

The fire design loads for the 12 storey model, Combination $2+3+4$ (from Table 4.7), are listed in Table 4.9. Only the worst effected columns are looked at, and the utilisations of the cross sections are found in Table 4.10. Tables for loads and utilisation for the six and seven storey model are found in Appendix C.

Table 4.9: Fire design loads, 12 storeys n12d6, Combination $2+3+4$

| Column <br> eff. cross section [mm $\times \mathrm{mm}$ ] |  | $\begin{aligned} & M_{z} \\ & {[\mathrm{kNm}]} \end{aligned}$ | $\begin{aligned} & M_{y} \\ & {[\mathrm{kNm}]} \end{aligned}$ | $\begin{aligned} & V_{z} \\ & {[\mathrm{kN}]} \end{aligned}$ | $\begin{aligned} & V_{y} \\ & {[\mathrm{kN}]} \end{aligned}$ | $\begin{aligned} & N \\ & {[\mathrm{kN}]} \end{aligned}$ | $\begin{aligned} & P \\ & {[\mathrm{kN}]} \end{aligned}$ |

| C.11b | $33 \%$ | $38 \%$ | $28 \%$ | $64 \%$ |

### 4.1.3 Variation of slabs

The footprint of the main model is altered by adding and removing slabs. The first variation is adding slabs in the z-direction, maintaining the Room Corridor Room Design. Then there is looked at a variation with only one open section (only "Room") for 12 slabs.

## Acceleration

Table 4.11 and 4.12 lists the frequencies and accelerations for the different modifications.

Table 4.11: Frequencies and accelerations, n8d10, n8d12

|  | Modification | Mass [kg] |  | Frequency [ Hz ] |  | Acceleration [m/s ${ }^{2}$ ] |  |  |  |

| Base | 92.6 | $93 \%$ | 26.6 | $-45 \%$ |
| Combination 3 + 4 | 43.1 | $-10 \%$ | 10.2 | $-79 \%$ |

## Fire design

The fire design loads are calculated for the n8d12 model, Combination $3+4$ (from Table 4.11). The worst effected columns are listed in Table 4.14, and the utilisation of the cross sections are found in Table 4.15. The RCR n8d10 and n8d12-room models have similar low utilisation and the tables for loads and utilisation are found in Appendix C.

Table 4.14: Fire design loads, n8d12, Combination $3+4$

### 4.1.4 With shaft, n8-shaft

## Acceleration

The model presented in Figure 4.6a has a shaft coupled to the structural system. Table 4.16 lists the frequencies and accelerations for the different modifications for the model with shaft. Table 4.17 shows the effect of removing the exterior shear walls, hence the stability is then only provided by the shaft and the moment resisting frames. This model is shown in Figure 4.6b

(a) With shaft and shear walls

(b) Only shaft

Figure 4.6: The first mode shape (x-direction) of the RCR n8-shaft model, with and without shear walls

## Four storeys on top of an existing building

This configuration is used to investigate the interaction between the existing building and the new four storey timber building. The following three cases are looked into:

1. Existing building has lower natural frequency than the added timber part
2. Existing building in resonance with the added timber part
3. Existing building has higher natural frequency than the added timber part

Only the results from case three are presented in Table 4.26, see Figure 4.9. The virtual existing building consist of five storeys.

## 4．2 Design：T－shape

The results for the T－design models are presented in this section．The main model is presented thoroughly with results for many modifications．The main model is followed by the most important results from the models with variation of number of slabs，addi－ tional shafts and a six storey model．

## 4．2．1 Main model

## Acceleration

Table 4.27 presents the frequencies with corresponding acceleration for the main model． The three first eigenmodes are shown in Figure 4．10．The T－design models have tor－ sional eigenmodes，which as mentioned in Section 2．5，should not be used in the accel－ eration calculation method from NS－EN 1991－1－4．

Figure 4．10：First three eigenmodes of the main model in T－design

Table 4．27：Frequencies and acceleration，T－design main model

| Eigenmode | Frequency $[\mathrm{Hz}]$ | Type | Acceleration，$a\left[\mathrm{~m} / \mathrm{s}^{2}\right]$ |
| :--- | :--- | :--- | :---: |
| 1 | 0.791 | Translation | 0.154 |
| 2 | 0.844 | Torsion | - |
| 3 | 0.889 | Torsion | - |

Table 4.28 presents the acceleration for different parametric changes from the main model，alongside the deviations from $0.04 \mathrm{~m} / \mathrm{s}^{2}$ ．The table also includes the values
for model total mass, effective mass and frequency for the translation eigenmode in x -direction.

Table 4.28: Frequencies and acceleration, T-design main model

| Modifications | Mass [kg] |  | Frequency [Hz] |  | Acceleration, $\boldsymbol{a}\left[\mathrm{m} / \mathrm{s}^{2}\right]$ |  |  |
| :--- | :--- | ---: | ---: | :---: | ---: | ---: | ---: | ---: |
|  | Total | $m_{e}$ | x -dir | x-dir | $\Delta a / 0.040$ | $\Delta a / a_{\text {main }}$ |  |
| 1 | Base $^{8}$ | 698123 | 29088 | 0.791 | 0.154 | $285 \%$ | $0 \%$ |
| 2 | $t_{\text {shear }}=180 \mathrm{~mm}$ | 710461 | 29603 | 0.826 | 0.145 | $261 \%$ | $-6 \%$ |
| 3 | $k_{\text {rot }}=20000 \mathrm{kNm} / \mathrm{rad}$ | 698123 | 29088 | 0.844 | 0.143 | $258 \%$ | $-7 \%$ |
| 4 | $\rho$ doubled top two floors | 836018 | 42793 | 0.641 | 0.135 | $241 \%$ | $-11 \%$ |
| 5 | $30 \%$ live load added as mass | 1019412 | 42475 | 0.639 | 0.137 | $238 \%$ | $-12 \%$ |
| 6 | Cross section $210 \times 675$ | 759889 | 31662 | 0.942 | 0.117 | $193 \%$ | $-24 \%$ |
| 7 | Cross section $280 \times 900$ | 846360 | 35265 | 1.088 | 0.090 | $125 \%$ | $-42 \%$ |
| 8 | BC: $k_{\text {rot }}=10000 \mathrm{kNm} / \mathrm{rad}$ | 698123 | 29088 | 0.768 | 0.159 | $297 \%$ | $3 \%$ |
| 9 | BC: pinned | 698123 | 29088 | 0.741 | 0.165 | $313 \%$ | $7 \%$ |

## Deflection

The deflections have been checked for the modifications with the lowest accelerations and are listed in Table 4.29. The deviation from the requirement of 48 mm for a 24 m high building is also included.

Table 4.29: Deflection, T-design main model

| Modification | Deflection $[\mathrm{mm}]$ |  |  |  |
| :--- | ---: | ---: | ---: | ---: |
|  | U1 | $\Delta U 1 /_{\max }$ | U3 | $\Delta U 3 /{ }_{\max }$ |
| Base | 93.2 | $95.7 \%$ | 67.5 | $40.7 \%$ |
| $\rho$ doubled top two floors | 92.9 | $93.5 \%$ | 69.1 | $44.0 \%$ |
| Cross section $210 \times 675$ | 60.4 | $25.8 \%$ | 45.7 | $-4.8 \%$ |
| Cross section $280 \times 900$ | 41.9 | $-12.7 \%$ | 32.0 | $-33.3 \%$ |

## Fire design

The fire design loads are listed in Table 4.30. The worst effected columns are presented, and the utilisation of their cross sections are listed in Table 4.31. For the T-design models, the most vulnerable columns are the outer corner columns and the columns between the flange and the web, illustrated in Figure 4.11a. The corner columns have an initial cross section of $140 \mathrm{~mm} \times 450 \mathrm{~mm}$ and are reduces by fire load on two sides. The
columns between flange and web have an initial cross section of $280 \mathrm{~mm} \times 450 \mathrm{~mm}$ and are reduced by fire load on all four sides. Figure 4.11b illustrates the axis system used for fire design.

Figure 4.11: Column grouping and axis system

### 4.2.2 Adding slabs, n8-long-web

## Acceleration

The accelerations, mass and frequency for the different modifications of model n8-long-web, Figure 4.12, are presented in Table 4.32. The results from the main model are presented for comparison.

Figure 4.12: The first mode shape for the n8-long-web model

Table 4.32: Frequencies and accelerations, n8-long-web, see figure 4.12

| Modification | Mass [kg] |  | Frequency [Hz] |  | Acceleration, $\boldsymbol{a}\left[\mathrm{m} / s^{2}\right]$ |  |  |
| :--- | ---: | ---: | ---: | :---: | ---: | ---: | ---: |

### 4.2.3 Adding shaft, n8-shaft

## Acceleration

By adding a shaft to the T-design, the model becomes unsymmetrical about both axis. The eigenmodes of the model are therefore not pure translation. To calculate accelerations for the models with a shaft, the mode closest to translation in the x-direction is used. The mass activated is $64 \%$ of the total mass, with 401 out of 623 tons. These numbers are extracted from Abaqus, and do not fluctuate much for the other modifications of the shafted models. Figure 4.13 shows the torsion modes for the basic model.

Figure 4.13: Torsional modes used as translation modes

The frequency, mass and acceleration for the modifications are presented in Table 4.36. The results from the main model are presented for comparison.

Table 4.36: Frequencies and accelerations, shear models, n8-shaft and n8-shaft-shear

|  | Modification | Mass [kg] |  | Frequency [Hz] x-dir | Acceleration, $\boldsymbol{a}\left[\mathrm{m} / \mathrm{s}^{2}\right]$ |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## Chapter 5

## Summary of Results and Discussion

This chapter includes a short summary of the results followed by discussion of the findings and a section on sources of error.

### 5.1 Summary of results

The results from the main model of each design show that the acceleration is far from the ISO-requirement of $0.04 \mathrm{~m} / \mathrm{s}^{2}$. The RCR base model has an acceleration of 0.080 $\mathrm{m} / \mathrm{s}^{2}$ in the x -direction and $0.134 \mathrm{~m} / \mathrm{s}^{2}$ in the z -direction (Table 4.1). The T -design base model has an acceleration of $0.154 \mathrm{~m} / \mathrm{s}^{2}$ (Table 4.28 ). For the same models, neither the deflection nor fire requirements are met. The deflection requirement is 48 mm for the 24 m building. For the RCR base model the deflection is no problem in the direction of the frames, but 61 mm in the shear wall direction (Table 4.2). For the T-design base model the deflection is 93.2 mm in x -direction and 67.5 mm in the z -direction (4.29). With the cross section dimensions of the base models, the capacity under fire load is exceeded (Table 4.4 and 4.31), and the cross sections need to be increased to meet the requirement.

Based on the results from the main models, the focus is to decrease the acceleration. The acceleration requirement is believed to be the most difficult to reach. This assumption is supported by experience from other projects on tall timber buildings [3] [40]. After achieving a lower value for the acceleration, the deflection and fire design are
checked with the same modification of parameters, and proven for most of the models to be satisfactory.

The results show that increasing the cross sections of the columns will have a large impact on the acceleration (Table 4.1 and 4.28). A large effect is also seen from adding shear walls, shafts and extra mass. Some modifications where only checked for the main models, e.g. the increase of rotational stiffness, change of boundary conditions, and changing the thickness of the shear walls. All parameters will be discussed to a greater or lesser extent in the following section.

### 5.2 Discussion

### 5.2.1 Parametric study

## Cross section of columns

By increasing the height and width of the cross sections of the columns with a factor of $n$, the second moment of inertia, $I$, will increase by a factor of $n^{4}$. This can be seen from equation $I=\frac{b \cdot h^{3}}{12}$, for a rectangular cross section with sides $h$ and $b$. By comparing the columns with cantilevers from the beam formulas, with stiffness $k=\frac{8 E I}{L^{4}}$, it is clear that an increase in $I$ will result in a larger stiffness contribution from the columns. The beam formula is shown in Figure 5.1. This can be seen in the eigenfrequencies and consequently the accelerations for all models in Chapter 4. E.g. for the RCR main model, where doubling the dimensions of the cross section leads to a decrease in accelerations of $41 \%$ in the $x$-direction and $46 \%$ in the $z$-direction (Table 4.1 ). Other welcomed effects of the increase of cross section are the reduced deflections in the top floor and higher capacity during fire.

Figure 5.1: Formulas for a cantilever beam [2]

## Mass

When the mass increases and the stiffness is kept unchanged, the eigenfrequency decreases. A lower eigenfrequency has a negative effect on the acceleration, while the in-
crease of mass has a positive effect. The contribution from increased mass has a greater impact on the acceleration than the decrease of frequency. The decrease of acceleration can be explained by Newtons second law; $F=m \cdot a$, where $F$ is force, $m$ is mass and $a$ is acceleration. Newtons second law can be rewritten to $a=F / m$, where it becomes obvious that increasing mass decreases the acceleration, since the force at an arbitrary point is constant.

The results from Chapter 4 show that the relative decrease in acceleration is approximately the same if the density of the top two floors are doubled, as the effect of adding $30 \%$ of the live load as extra mass in the modal analysis. For the T-design main model, the acceleration decreased by $11 \%$ when the density of the top two floors are doubled, and $12 \%$ for including $30 \%$ of the live load as extra mass (Table 4.28). The increase of total mass from these modifications are 138 and 321 tons, respectively. Even though the effect is more or less the same, it is advisable to add mass to the top of the building rather than a evenly distributed mass over the whole building. A low total mass means lower reaction forces, hence have a positive impact on the fire design as well as the amount of needed foundation.

The advantage of adding mass at the top of the building can be explained by the formula used to calculate the equivalent mass, $m_{e}$ (Equation (2.7)). $m_{e}$ is a function of the product of the mode shape and the distributed mass over the height of the building. The highest value of the mode shape is at the top of the building (Figure 5.2a), while the mass can be represented as evenly lumped mass to the floors, as illustrated in Figure 5.2 b . Hence the mass added on the top of the building has a greater influence on the acceleration.

Figure 5.2: Illustration of distributed mass and mode shape

## Shear walls and shaft

The adding of shear walls will greatly affect the stiffness in the plane direction of the wall. For the RCR main model it is shown that the acceleration in the $x$-direction decreases by $23 \%$ when two shear walls are added (Table 4.1). The decrease is in the same
range for the T-design main model (Table 4.40). The effect can also be seen for the RCR model with shaft and shear walls, compared to the same model with only shaft. These results show that by removing the four shear walls, the acceleration increases by $40 \%$ (Table 4.17). For the T-design model with added shaft, the adding of a shear wall have a modest influence of $2.6 \%$ (Table 4.36). This is because the shaft is modelled with a 5 ply CLT, which takes up a large part of the forces due to its large capacity, thus dominating the stability contribution. Adding a shaft and connecting it to the support system will have a positive influence on the acceleration for all models, but there are some drawbacks connected to it. By adding a shaft to the model, some of the robustness is lost, as the results are dependent on the exact size and location of the shaft.

Doubling the thickness of the shear walls has a positive effect on the acceleration. 9 \% for the RCR main model and 6.2 \% for the T main model (Table 4.1 and 4.28). This contribution is not considered big enough compared to the alteration, and not investigated further. The shear walls have been placed in the corners of the buildings. This is not favourable as these areas can be used to let sunlight into the building, and thus should not be closed off by shear walls. The effect of placement of the shear walls has not been investigated in this thesis.

## Rotational stiffness

To study the effect of the rotational stiffness in the connections between beams and columns, the RCR design is used. This model has columns all oriented the same way, making the discussion on the effect easier, while the T-design models have columns oriented orthogonal with respect to each other in the flange and the web part. Based on this, the results from Table 4.1 are used.

With a doubling of rotational stiffness, the acceleration decreases in the frame direction by $13 \%$ and $1 \%$ in the $z$-direction. This makes sense, given that the connections have rotational stiffness about the $z$-axis, and all other rotational degrees of freedom are released. The frequency rises with increased stiffness and makes the acceleration, as well as the deflection, decrease. This effect is welcomed, but as already stated, not taken into further investigation on the customised models. This decision is based on available knowledge on the matter, stating the possibility to achieve a rotational stiffness of about $10000 \mathrm{kNm} / \mathrm{rad}$ [13] [20]. This is a topic under investigation, and if further research makes it possible to achieve higher rotational stiffness. This will have a positive effect on the acceleration and displacement in the frame direction of the building concept considered in this thesis. However, the connection can not be stiffer than a rigid connection, and a further increase of the rotational stiffness is assumed to stagnate when closing in on a rigid behaviour.

For the T-design main model, the decrease in acceleration for doubling $k_{r o t}$ is $6.9 \%$ in the x -direction (Table 4.28). The deviation from RCR can be explained by number of effective moment resisting connections in the x -direction for the two models. The main model of RCR design has a total of 576 single connections to slabs in x-direction, while the main model of the T-design has 320 . Hence the RCR design has 1.8 times more connections than the T-design. By multiplying the decrease in the T model by 1.8, the result is $12.4 \%$, which is about the same as the $13 \%$ from the RCR design.

## Number of storeys

The effective mass, $m_{e}$, (from Equation (2.8)) remains unchanged by adding or removing storeys of the building, given that all other parameters stays unaltered and that the simplified calculation $m_{e}$ is used. From the beam formulas in Figure 5.1, it is clear that the stiffness will be influenced by the height, $L$, loosing stiffness for increasing height. This can be seen when comparing the building to a cantilever with stiffness $k=\frac{8 E I}{L^{4}}$ for a uniform line load. This tendency is clear in the graph from Figure 5.3.

Figure 5.3: Graph of acceleration for the varying number of storeys

## Variation of slabs

(a) RCR 12 slabs

(b) Room 12 slabs

(c) T long web

(d) T long flange

Figure 5.4: Models with added slabs

The models in Figure 5.4 have in common that the footprints have been changed from the main model of their design type. This has been done by adding or removing frames and slabs. It is difficult to draw a conclusion of the effect of adding or removing slabs and frames alone. These changes affect a lot of parameters, like mass, stiffness, footprint and building slenderness, which again influence variables used in the formula for calculating the acceleration (Equation (B.1)).

Figure 5.5: Models with open first floor

Figure 5.5 shows the RCR models with an open first floor, with results presented in Section 4.1.6. These models give a better view on the contributions from slabs. The results show that the acceleration is unaltered in the x-direction by removing only the slabs from the first floor (Table 4.25). To discuss the effect the removal of slabs have on the building, it is necessary to compare the global stiffness of the modified model with the main model. The global stiffness can be found by rearranging the basic formula for frequency to $K=\omega^{2} \times M$. As mentioned, the acceleration is unaltered between the two models, but both the mass and the frequency have decreased by removing the slabs. As a consequence, $K$ from the formula must have decreased as well, resulting in a lower global stiffness for the modified model. The reduced stiffness is caused by removing slabs, making utilisation of the slab stiffness impossible.

The acceleration increases with $8 \%$ when both slab and beams are removed. The cause for the increased acceleration is the removal of connections with rotational stiffness, as discussed in the section for rotational stiffness. The effect of removing slabs and beams can be neglected in the z -direction, because the horizontal stability provided from the frames mainly affects the x -direction. This is supported by the findings summarised in Table 4.25, as the changes are in the magnitude of 1-2 \%.

## Boundary conditions

All base models are modelled with encastred boundary conditions for the columns. This is the stiffest connection type, and a change of the restrain have a negative ef-
fect on acceleration and deflection results. For the RCR main model, the acceleration is increased in the $x$-direction by $8 \%$ for a semi-rigid condition with a rotational stiffness of $10000 \mathrm{kNm} / \mathrm{rad}$, and $21 \%$ for the pinned connection (Table 4.1). In the z direction, the effect is negligible. This is expected as the shear walls will distribute the forces into pressure and tension when the pinned connection prevents moment forces, and the stiffness in this direction is in a large extent due to the shear walls. In the $x$ direction however, the stiffness is only provided by the moment resisting frames, hence more influenced by the change of boundary condition. When the boundary condition is pinned, only the stiffness contribution from the frames are included. For the T-design main model, the increase in acceleration is $3.2 \%$ for semi-rigid and $7.2 \%$ for pinned (Table 4.28). The difference in impact for the T-design model can be explained by the shear walls spanning in both directions, giving a contribution to the stiffness and makes the boundary conditions less critical.

## Fire design and deflection requirement

The calculation of capacity under fire is done, assuming no extra measures to gain fire protection of the columns. This is a conservative assumption as measures like fire paint or gypsum plates can be used to increase fire resistance. The fire capacity does not change drastically for some of the parametric changes, as e.g. increasing rotational stiffness or shear wall thickness. These changes will alter the force distribution, but not enough to make the big differences. However, by adding mass or increasing number of storeys, the forces will increase, and the fire requirements will be harder to reach. The change of most influence is the increase the columns cross sections. This will lead to a larger effective cross section after 90 minutes of fire, having a great impact on the second moment of inertia. The fire requirements are easily met by increasing the cross section. As seen in the fire capacity tables throughout Chapter 4 the increase of cross section is essential.

Increasing the cross section also has positive effect on deflections. By doubling the cross section dimensions, the deflection in the x-direction is reduced by $41 \%$ for the RCR main model, and $42 \%$ for the T-deign (Table 4.2 and 4.29). The same is seen for the z-direction. For other parameters, a decrease of stiffness in the structure will increase the deflections, while an increase of stiffness will have the opposite effect. Changing the boundary conditions from encastred to pinned, increased the deflection from 38.8 to 51.1 mm in the x -direction (Table 4.2). For simplicity, this effect can also be explained with the beam formula for a cantilever beam with uniform line load from Figure 5.1, where it becomes clear that an increase in stiffness will decrease the deflection.

### 5.2.2 Other interesting variables

The damping of the models, $\xi$, is set to $1.5 \%$ in the acceleration calculations, giving a structural damping $\delta_{a}=0.0943$. This value is chosen based on results from comparable timber buildings like Moholt 50|50 in Trondheim and Treet in Bergen [31]. If the actual damping is different from $1.5 \%$, the acceleration is affected. E.g. with a damping of 2.0 $\%$, the acceleration for the RCR main model drops from 0.080 to $0.069 \mathrm{~m} / \mathrm{s}^{2}$ in the frame direction, a decrease of $12.7 \%$. In the z-direction, the acceleration drops from 0.134 to $0.117 \mathrm{~m} / \mathrm{s}^{2}$, a decrease of $12.6 \%$.

The reference wind speed has a large effect on the acceleration calculated. The reference wind speed from Trondheim is $26 \mathrm{~m} / \mathrm{s}$. If the building was set to Oslo, where the reference wind speed is $22 \mathrm{~m} / \mathrm{s}$ (see Appendix A.4), the acceleration for the main model of the T-design would drop from 0.154 to $0.091 \mathrm{~m} / \mathrm{s}^{2}$, a decrease of $40.9 \%$, making this a very important parameter.

A few geometrical parameters have not been investigated. These include storey height, slab length and slab orientation. The storey height used in the analysis of 3 m can be too low, given that the slab thickness is yet to be decided and the lowest net height in a residential building is 2.4 m [42]. If the height increases, the stiffness will decrease, resulting in a higher acceleration. Increasing the storey height will also increase the buckling lengths of the columns, influencing the columns capacity.

Using shorter slabs will enable lower thickness, and ease satisfaction of serviceability requirements. The storey height is also less critical the thinner the slabs. If the slabs are oriented orthogonal with respect to the frames to get larger open column-free areas, they will not contribute to the horizontal bracing of the building. Another consequence is that there will be fewer columns per metre and fewer connections, making the structure less stiff in the frame direction. The accelerations and deflections will increase and the columns will have to take more forces, probably leading to the necessity of other measures to get the results within the requirements.

### 5.2.3 Adding storeys on existing building

Figure 5.6: Four storeys on top of a virtual building

Adding storeys on an existing building is an interesting application due to the low density of wood. Figure 5.6 shows the model analysed. A four storey building was added on top of a building modelled to have a higher natural frequency. By increasing the cross section height of the column to 585 mm , and by using $30 \%$ of the live load in the modal analysis, are sufficient to meet the acceleration criteria on $0.04 \mathrm{~m} / \mathrm{s}^{2}$ (Table 4.26). The base model with extra mass, with the original cross section of $140 \times 450 \mathrm{~mm}$, gives an acceleration of $0.045 \mathrm{~m} / \mathrm{s}^{2}$, which can be argued to be acceptable.

As mentioned in Section 4.1.6, three different cases where investigated. The natural frequency of the extended building is determined by the part with the lowest frequency. The most beneficial situation is when the added part has the lowest frequency. This case can be simplified to a situation where the added part behaves like the existing building is the ground foundation, due to the pinned connection between the two buildings. In other words, the added part behaves more or less independent from the existing one. When the frequency of the existing part is either lower or in resonance with the added part, the interacted frequency drops and thus makes it more difficult to meet the acceleration criteria. However, it has to be emphasised that this is a preliminary study, and a more detailed consideration is needed to find the exact interaction effect.

### 5.2.4 Acceleration requirement

As mentioned in Section 2.5.1, the acceleration requirement is not actually a requirement, but used as a guideline. It can be argued for designing buildings with an acceleration higher than the limits in the ISO-curve (see Figure 5.7). From Table 2.4, a new limit of $0.05 \mathrm{~m} / \mathrm{s}^{2}$ can be adopted. As the perception level limits work as a guideline, the construction client stands free to decide the requirement for each project. This means that for example the T-design model with shaft and modification 7 or 8 from Table 4.36
can be considered, giving a simulated acceleration of $0.055 \mathrm{~m} / \mathrm{s}^{2}$ and $0.045 \mathrm{~m} / \mathrm{s}^{2}$, respectively.

Figure 5.7: Evaluation curves for wind-induced vibrations [9]

### 5.2.5 Simplifications and sources of error

## Slabs

The simplification of the slabs includes two steps, both bringing potential errors to the results of the calculations. First modelling the slab based on another model with possible errors of its own as explained in Section 3.3.5, and then the combining of several slabs with a weak partition in between slabs as one part in Abaqus.

The simplification of the slab is done for a single slab, this means that the frequencies and deflections that corresponded between the models might be altered when several slabs are put together as one part. However, the partition is so weak, that it is believed that the slabs are close to working independently. This is confirmed by checking the moment distribution for the RCR main model with wind in x-direction, where every column has the same moment about the $z$-axis. The connection between slabs will probably be made by screws in a constructed building, giving some stiffness between neighbouring slabs. This issue may cause a deviation between reality and simulation.

## Shear walls and shaft

The shear walls are modelled in Abaqus by merging shear wall parts with full length columns. This results in a shear wall spanning over the entire height of the model. In reality the shear wall will probably consist of storey high parts, connected to each other and the rest of the structural system. This solution is better for the acoustic properties by reducing the flanking transmission. Storey high shear walls will cause a different force distribution and give a different stiffness which can impose errors in the acceleration and deflection simulations. Another limitation to the model is that only shear and
bending modes of the shear walls are simulated, not the anchorage slip, which is often governing [41]. The same limitations applies to the modelling of shafts. In addition, there has not been looked into openings in the shear walls or shafts for e.g. doors and windows, which will affect the stiffness contribution.

## Wind modelling

The wind distribution used is in this work is a simplification of the distribution from NS-EN 1991-1-4. The simplification in the wind modelling gives a uniform wind field on each side of the building, with no variation over the height and no wind forces on the roof. A brief test was done including forces on the roof (see Appendix A.4.4). The results had little influence on the acceleration and deflection, thus making the wind forces on the roof negligible in this thesis. The other simplifications of distribution are considered conservative.

The details of the distribution are found in Section 2.4.4. It is also important to note that the method in the Eurocode is a simplification. Both with respect to simplification of the geometry for the building and the calculation of wind forces; assuming the wind to be a static load, only blowing orthogonal on one side of the building. Wind is a dynamic action, and the structural factor $c_{s} c_{d}$ is used to simplify the wind to be a static force.

## The T-shape

Figure 5.8: First mode of T-design n8-shaft

The T-design models that are symmetric about the x -axis, have an eigenmode dominated by translation and can be used in acceleration calculations. For the models with a shaft added, the eigenmode used in the acceleration calculations is less dominated by translation, hence the results from calculations can include errors. The eigenmode for one shaft model is shown in Figure 5.8 and has an activated mass of $64 \%$ in the x -direction. This is not ideal, and wind tunnel testing is recommended.

The T-design has a too complicated geometry for the simplified method in NS-EN 1991-1-4. To calculate wind loads for these models, a fictive rectangular shape encapsulating the building has been used. The actual wind distribution for the building will be different from the one used and this can cause deviations between the simulations and the reality.

## Abaqus mesh

The investigation on the effect of different mesh sizes in the finite element analyses has been brief. There has been run a few simple models with finer mesh to learn how the results was influenced. The frequencies did not change with more than a few percent for a finer mesh. For the amount of simulations done during this thesis, it was of great importance that the computational time was low. This was done by keeping the mesh size relatively coarse, with a possible consequence of reduction in exactness of the solutions.

## Chapter 6

## Conclusions and Further Work

Based on the results from Chapter 4 and the discussion from Chapter 5, some conclusive remarks on the work are made, followed by some recommendations for further work.

### 6.1 Conclusion

As expected, the main obstacle to overcome working with these timber buildings was the acceleration requirements. For the main model of each design, the best result was $0.08 \mathrm{~m} / \mathrm{s}^{2}$ for the RCR design, being the exact double of the requirement from the ISO curve, of $0.04 \mathrm{~m} / \mathrm{s}^{2}$.

The parametric study showed that a lot can be done to decrease the accelerations to better levels. The response of a building is dependent on the typology, as well as design solutions like connections and boundary conditions. It has been shown that the most effective change is to increase the size of the column sections, represented by the results for the T-design main model, which had its acceleration drop by $41.5 \%$ by doubling the dimension of both sides of the columns. By adding shear walls to a design, an effective improvement of the results has been seen. This is represented by the main model of the RCR design, where the acceleration decreased by $23 \%$ after adding a shear wall pair. Shafts also have an important contribution, as they work similarly to shear walls if connected to the support system. The RCR main model has $31 \%$ higher acceleration in the x -direction compared to the same model with a connected shaft. In the z -direction, the acceleration is $67 \%$ higher.

For deflections, the results of this thesis show that the requirements are met as long
as the acceleration requirements are. Besides lowering the number of storeys, the increasing of the column sections is the most important factor to decrease the deflection. These parameters are also the most important regarding the fire capacity, which is satisfactory for the models and modifications where the acceleration and deflections are within their requirements.

An important remark is that the acceleration requirements are considered a guideline, and the construction client has to set the limits for the individual project. Also, the effect of the reference wind speed and the damping ratio has a great impact on accelerations, and should be considered for the individual project.

Based on the results from this thesis, it can be concluded that it will be possible to build high-rise timber buildings using the structural system with moment resisting frames bracing the building in one direction. With the requirements for acceleration, deflection and fire capacity met. By combining different modifications, like increasing column cross sections, including a shaft as a part of the support system or adding mass to the higher floors, the system can be used to build eight storeys high buildings, and probably higher.

### 6.2 Recommendations for further work

The structural system based on moment resisting frames for timber buildings has not been investigated to a great extent in the past, hence there are a lot of parameters which influence can be mapped. During the work of this thesis, some parameters have been investigated more than others. To improve the exactness of the results, and to get a better understanding on the issues investigated in this thesis, recommendations on topics to look further into are presented here.

## Geometrical changes

The storey height of the models investigated are all 3 m high. Changing the height of the columns will influence both capacity and results on acceleration and deflection. The impact of this parameter should be studied in greater detail as it is believed that this is a parameter that might be changed, as discussed in Section 5.2.2.

The span length and span orientation of the slabs will influence the dynamic properties of the models. The effect of using shorter or longer slabs have not been considered in this thesis, but is not believed to be negligible. Investigating the effect from using shorter slabs might not be that interesting, given the goal of large open spaces for the WoodSol project. Orienting the slabs so that the span direction is orthogonal to the frame span is more interesting, as this will rise the possibility for larger open areas. The negative effects discussed previously of this change are important to map.

## Shear walls and bracing

The effect of the placement of shear walls have not been investigated. The problems on loss of daylight in valuable areas for apartments makes this a topic worth looking into. In addition to the placement of the walls, it should be investigated other ways of bracing. Glass plates used to stiffen a building is a possibility, or multi-storey spanning timber trusses.

It is recommended to look further into the modelling of the connection between shear walls and columns. This should be done to investigate the influence of the anchorage slip mode, and maybe get more accurate results on shear wall contribution.

## Seismic performance

The seismic actions have not been given any consideration in this thesis due to the assumption that the governing horizontal load action arises from the wind. The seismic
performance will be of greater importance for low-rise buildings due to higher natural frequency and thus lower natural period, which is more likely to coincide with the natural period of an earthquake. However, due to Eurocode regulations, new building projects must include seismic design considerations.

## Assembly and model testing

Assembly on site is of great interest for realisation of this project. One of the goals stated for the WoodSol project is rapid erection on site.

In addition to rapid erection, the tolerance requirements for the assembly of frames and slabs should be emphasised. Some sort of temporary bracing may be needed to assure the required tolerance limit, even though the rotational stiffness of the boundary condition are approaching an clamped situation.

Model testing of a full scale model would be useful to ensure that the structural system behaves like it is modelled. This full scale model could for instance include two storeys and two slabs. In a potential model testing, one should emphasise the behaviour of the moment resisting frames, stabilisation effect from the slabs and contribution from the shear walls.

## Appendix A

## Loads

## A. 1 Load cases

Table A. 1 gives an overview of the $\psi$-factors, while Table A. 2 gives load combinations.
Table A.1: Overview $\psi_{0}$, from NS-EN 1990 [23]

|  |  | $\psi_{0}$ | $\psi_{1}$ | $\psi_{2}$ |
| :--- | :--- | :---: | :---: | :---: |
| A | Residential areas | 0.7 | 0.5 | 0.3 |
| B | Office areas | 0.7 | 0.5 | 0.3 |
| C | Congregation areas | 0.7 | 0.7 | 0.6 |
| D | Shopping areas | 0.7 | 0.7 | 0.6 |
|  | Snow | 0.7 | 0.5 | 0.2 |
|  | Wind | 0.6 | 0.2 | 0.0 |

Table A.2: Load combination from NS-EN 1990 [23]

|  | Permanent load |  | Dominant variable | Remaing variable <br> loads |
| :--- | :---: | :---: | :--- | :---: |
| Favorable | Unfavorable | load | $1.50 / 0 \cdot \psi_{0, i} Q_{k, i}$ |  |
| Eq (2.3a) | $1.35 \cdot G_{k j, \text { sup }}$ | $1.00 \cdot G_{k j, \text { inf }}$ | $1.50 / 0^{1} \cdot \psi_{0,1} Q_{k, 1}$ | $1.50 / 0 \cdot \psi_{0, i} Q_{k, i}$ |
| Eq (2.3b) | $1.20 \cdot G_{k j, \text { sup }}$ | $1.00 \cdot G_{k j, \text { inf }}$ | $1.50 / 0 \cdot Q_{k, 1}$ |  |

[^10]
## A. 2 Live load

Table A. 3 show examples of a buildings intended use and the associated live load.
Table A.3: Live loads, from NS-EN 1991-1-1 [24]

|  | Distributed load $\mathrm{kg} / \mathrm{m}^{2}>\mathrm{kg} / \mathrm{m}^{2}$ | Concentrated load <br> $[\mathrm{kN}]$ |
| :--- | :---: | :---: |
| Residential, floor | 2 | 2 |
| Office building | 3 | 2 |
| Schools, restaurants | 3 | 4 |
| Shopping areas | 5 | 4 |

## A. 3 Snow load

The Equation (A.1) for snow load is found in NS-EN 1991-1-3 [25]. The shape of the roof decides the reduction factor $\mu_{1}$. For this work, the assumption of a flat roof is used, which gives $\mu_{1}$ equal 0.8, see Figure A.1. Snow loads for a selection of Norwegian cities are listed in Table A.4. Further investigations are required for either pitched or multispan roofs. Note: $s$ is referenced to as $s_{k}$ in Section 2.4

$$
\begin{equation*}
s=\mu_{1} \cdot C_{e} \cdot C_{t} \cdot s_{k} \tag{A.1}
\end{equation*}
$$

where

$$
\begin{align*}
& s_{k}= \begin{cases}s_{k, 0} & \text { if } H<H_{g} \\
s_{k, 0}+n \Delta s_{k} & \text { if } H>H_{g}\end{cases}  \tag{A.2}\\
& n=\frac{H-H_{g}}{100}
\end{align*}
$$

where

| $\mu_{1}$ | is the shape factor, equal 0.8 for a flat roof |
| :--- | :--- |
| $C_{e}$ | is the exposure factor, $C_{e}=1$ |
| $C_{t}$ | is the thermal factor, $C_{t}=1$ |
| $H$ | is the metres above sea level, see Table A. 4 |
| $H_{g}$ | is the ground height, equal 150 m |

Table A.4: Snow loads from NS-EN 1991-1-3 [25]

| City | $H / H_{g}$ <br> metres above sea level | $s_{k, 0}$ <br> $\left[\mathrm{kN} / \mathrm{m}^{2}\right]$ | $\Delta s_{k}$ <br> $\left[\mathrm{kN} / \mathrm{m}^{2}\right]$ |
| :--- | :---: | :---: | :---: |
| Oslo | $0-150$ | 3.5 |  |
|  | $151-250$ | 4.5 |  |
| Bergen | $251-350$ | 5.5 |  |
| Trondheim | $>350$ | 6.5 |  |
| Troms $\varnothing$ | 150 | 2.0 | 0.5 |

Figure A.1: Shape factor for snow load on roof, from NS-EN 1991-1-3 [25]

## A. 4 Wind load

The wind force is calculated by using Equations from NS-EN 1991-1-4 [26].
The internal and external forces, Equation (A.3), are added to find the resulting force on the building.

External and internal forces:

$$
\begin{align*}
F_{w, e} & =c_{s} c_{d} \sum_{\text {surfaces }} w_{e} A_{\text {ref }}  \tag{A.3a}\\
F_{w, i} & =\sum_{\text {surfaces }} w_{i} A_{\text {ref }} \tag{A.3b}
\end{align*}
$$

where

| $c_{s} c_{d}$ | is the structural factor, formulas for calculation in Section A.4.2 |
| :--- | :--- |
| $w_{e}$ | is the wind pressure on external surface at reference height $z_{e}$ |
| $w_{i}$ | is the wind pressure on internal surface at reference height $z_{i}$ |
| $A_{r e f}$ | is the reference area |

External and internal wind pressure:

$$
\begin{align*}
& w_{e}=q_{p}\left(z_{e}\right) c_{p e}  \tag{A.4a}\\
& w_{i}=q_{p}\left(z_{i}\right) c_{p i} \tag{A.4b}
\end{align*}
$$

where:
$q_{p}(z) \quad$ is peak velocity pressure at reference height, formulas for calculation in Section A.4.1
$c_{p} \quad$ is the pressure coefficient, formulas for calculation in Section A.4.3

## A.4.1 The peak velocity pressure

The peak velocity pressure $q_{p}$ is a function of the height and depends on the turbulence intensity $I_{\nu}$. The peak velocity pressure for a reference speed of $26 \mathrm{~m} / \mathrm{s}$ is shown in

Figure A.2.

Figure A.2: The calculated peak velocity pressure for a reference speed of $26 \mathrm{~m} / \mathrm{s}$

$$
\begin{equation*}
q_{p}=\left[1+7 \cdot I_{\nu}\right] \cdot \frac{1}{2} \cdot \rho \cdot v_{m}^{2} \tag{A.5}
\end{equation*}
$$

where
$\rho \quad$ is the air density, $\rho=1.25 \mathrm{~kg} / \mathrm{m}^{3}$
$I_{\nu} \quad$ is the turbulence intensity
$v_{m} \quad$ is the mean wind velocity

$$
\begin{gather*}
I_{\nu}(z)=\frac{\sigma_{v}}{v_{m}}=\frac{k_{l}}{c_{0} \cdot \ln \left(\frac{z}{z_{0}}\right)} \quad z_{\text {min }}<z<z_{\text {max }}  \tag{A.6}\\
I_{\nu}(z)=\frac{\sigma_{v}}{v_{m}}=\frac{k_{l}}{c_{0} \cdot \ln \left(\frac{z_{\text {min }}}{z_{0}}\right)} \quad z<z_{\text {min }} \tag{A.7}
\end{gather*}
$$

where
$\sigma_{\nu} \quad$ is the standard deviation of the wind velocity
$k_{l} \quad$ is the turbulence factor
$z \quad$ is the height for where the wind load is calculated
$z_{0} \quad$ for terrain category IV, $z_{0}=1$
$z_{\min } \quad$ is decided by $\min [16 \mathrm{~m} ; 0.6 \times H]$, for terrain category IV

The mean wind velocity $v_{m}$, is based on the reference wind velocity, $v_{b}$, at site. $v_{b}$, is dependent on the terrain, altitude, season etc. Most factors equal 1 , which is a conservative assumption [26].

$$
\begin{align*}
v_{m} & =c_{r} \cdot c_{0} \cdot v_{b}  \tag{A.8a}\\
v_{b} & =c_{\text {dir }} \cdot c_{\text {season }} \cdot c_{a l t} \cdot c_{p r o b} \cdot v_{b, 0} \tag{A.8b}
\end{align*}
$$

where

| $c_{r}$ | is the roughness coefficient |
| :--- | :--- |
| $c_{0}$ | is the terrain form factor, $c_{0}=1$ |
| $c_{\text {dir }}$ | is the directional factor, $c_{d i r}=1$ |
| $c_{\text {season }}$ | is the seasonal factor, $c_{\text {season }}=1$ |
| $c_{\text {alt }}$ | is the altitude factor, $c_{\text {alt }}=1$ |
| $c_{p r o b}$ | is the probability factor, $c_{\text {prob }}=1$ when return periode 50 years, equiv- <br> alent to $2 \%$ annual probability |
| $v_{b, 0}$ | is the reference wind velocity, Table A. 5 | Table A.5: Reference wind velocity for selected Norwegian cities

|  | $\nu_{b, 0}[\mathrm{~m} / \mathrm{s}]$ |
| :--- | :---: |
| Oslo | 22 |
| Bergen | 26 |
| Trondheim | 26 |
| Max Norway (Træna et al.) | 31 |

Terrain factor is IV represent city areas where $15 \%$ of the area is covered with building with average height over 15 metre. The terrain roughness decides the roughness coefficient, $c_{r}$

$$
\begin{gather*}
c_{r}(z)=k_{r} \cdot \ln \left(\frac{z}{z_{0}}\right) \quad z_{\text {min }}<z<z_{\text {max }}  \tag{A.9}\\
c_{r}(z)=k_{r} \cdot \ln \left(\frac{z_{\text {min }}}{z_{0}}\right) \quad z<z_{\text {min }} \tag{A.10}
\end{gather*}
$$

where
$k_{r} \quad$ is the roughness for the terrain, $k_{r}=0,24$ for terrian category IV

## A.4.2 The structural factor

The structural factor takes into account the dynamic response of the structure due to wind, a simplified method is to use the structural factor $c_{s} c_{d}$. The factor takes the effect of non-simultaneous occurrence of peak wind pressures on the surface together with the effect of the vibrations of the structure due to turbulence [26]. The procedure in Annex B in NS-EN 1991-1-4 is used the determine $c_{s} c_{d}$.

$$
\begin{equation*}
c_{s} c_{d}=\frac{1+2 \cdot k_{p} \cdot I_{\nu}\left(z_{s}\right) \cdot \sqrt{B^{2}+R^{2}}}{1+7 \cdot I_{\nu}\left(z_{s}\right)} \tag{A.11}
\end{equation*}
$$

where:
$z_{s} \quad$ is the reference height, $z_{s}=0.6 \cdot h \geq z_{\text {min }}$, see Figure A. 3
$k_{p} \quad$ is the peak factor
$I_{\nu} \quad$ is the turbulence intensity
$B^{2} \quad$ is the background factor, allowing the lack of full correlation of the pressure on the structure surface
$R^{2} \quad$ is the resonance response factor, allowing for turbulence in resonance with the vibration mode

Figure A.3: Structural dimentions and reference height [26]

The background factor:

$$
\begin{align*}
B^{2} & =\frac{1}{1+0.9 \cdot\left(\frac{b+h}{L\left(z_{s}\right)}\right)^{0.63}}  \tag{A.12a}\\
L\left(z_{s}\right) & =L_{t} \cdot\left(\frac{z}{z_{t}}\right)^{\alpha} \tag{A.12b}
\end{align*}
$$

where
$L\left(z_{s}\right) \quad$ is the turbulence length scale
$b, h \quad$ is the width and height of the structure
$L_{t} \quad$ is the reference length scale, $L_{t}=300 \mathrm{~m}$
$z_{t} \quad$ is the reference height, $z_{t}=200 \mathrm{~m}$
$\alpha \quad$ is $\alpha=0.67+0.05 \ln \left(z_{0}\right)$, where $z_{0}$ is the roughness length. $\alpha=0.67$ for $z_{0}=1$

The resonance response factor:

$$
\begin{equation*}
R^{2}=\frac{\pi^{2}}{2 \cdot \delta} \cdot S_{L}\left(z_{s}, n_{1, x}\right) \cdot R_{h}\left(\eta_{h}\right) \cdot R_{b}\left(\eta_{b}\right) \tag{A.13}
\end{equation*}
$$

where
$\delta \quad$ is the total logarithmic decrement of damping
$S_{L} \quad$ is the non-dimensional power spectral density function
$R_{h}, R_{b} \quad$ is the aerodynamic admittance functions
It is difficult to calculate the correct damping of a system. To know the exact damping of a structure a vibration experiment must be executed on the actual structure. Equation (A.14) gives an approximation of the damping:

$$
\begin{equation*}
\delta=\delta_{s}+\delta_{a}+\delta_{d} \tag{A.14}
\end{equation*}
$$

where
$\delta_{s} \quad$ is the logarithmic decrement of structural damping. Where $\xi$ is the
damping ratio for the building

$$
\delta_{s}=2 \pi \cdot \frac{\xi}{\sqrt{1-\xi^{2}}}
$$

$\delta_{a} \quad$ is the logarithmic decrement of aerodynamic damping for the fundamental mode. Where $c_{f}, n_{1, x}$ and $m_{e}$ are defined in Appendix B

$$
\delta_{a}=\frac{c_{f} \cdot \rho \cdot v_{m}\left(z_{s}\right)}{2 \cdot n_{1, x} \cdot m_{e}}
$$

$\delta_{d} \quad$ is the logarithmic decrement of damping due to special devices, $\delta_{d}=0$ for this project

$$
\begin{align*}
& R_{h}=\frac{1}{\eta_{h}}-\frac{1}{2 \cdot \eta_{h}^{2}}\left(1-e^{-2 \eta_{h}}\right)  \tag{A.15a}\\
& R_{b}=\frac{1}{\eta_{b}}-\frac{1}{2 \cdot \eta_{b}^{2}}\left(1-e^{-2 \eta_{b}}\right) \tag{A.15b}
\end{align*}
$$

with

$$
\begin{align*}
& \eta_{h}=\frac{4.6 \cdot h}{L\left(z_{s}\right)} \cdot f_{L}\left(z_{s}, n_{1, x}\right)  \tag{A.16a}\\
& \eta_{b}=\frac{4.6 \cdot b}{L\left(z_{s}\right)} \cdot f_{L}\left(z_{s}, n_{1, x}\right)[0.3 \mathrm{~cm}]  \tag{A.16b}\\
& S_{L}(z, n)=\frac{6.8 \cdot f_{L}(z, n)}{\left(1+10.2 \cdot f_{L}(z, n)\right)^{5 / 3}}  \tag{A.17a}\\
& f_{L}(z, n)=\frac{n \cdot L(z)}{v_{m}(z)} \tag{A.17b}
\end{align*}
$$

$f_{L}(z, n)$ is a non-dimensional frequency determined by the fundamental frequency $n=$ $n_{1, x}$ of the structure in $[\mathrm{Hz}]$.

## A.4.3 The pressure coefficient

The velocity pressure profile vary both vertically and horizontally. Each zone has a pressure coefficient $c_{p}$, see Table A.6. Figure A. 4 illustrate the different zones. A conservative simplification in this work, is not to vary the pressure profile over the height of the building and only use $q$ for $h$. Another simplification is to use only the zone with the highest wind pressure coefficient on the walls parallel to the wind direction. The wind pressure on the roof is neglected.

(a) Wind zones orthogonal to wind direction

(b) Wind zones for roof

(c) Wind zones perpendicular to wind direction

Figure A.4: Wind zones

Table A.6: External and internal pressure coefficients [26]

|  | A | B | C | D | E | F | G | H | I |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $c_{p e, 10}$ | -1.2 | -0.8 | -0.5 | 0.8 | -0.5 to -0.7 | -1.8 | -1.2 | -0.7 | -0.2 |
| $c_{p i, 10}$ | -0.3 | -0.3 | -0.3 | 0.2 | -0.3 | -0.3 | -0.3 | -0.3 | -0.3 |

## A.4.4 The calculated wind loads for each model

The wind loads for the models in this thesis, with some of the factors used for calculation and the resulting line load on the columns, are presented in this Appendix through Tables A. 8 to A.31. The wind loads presented are used for all modifications for the given model, and models with similar geometric properties. E.g. the loads from Table A. 29 are used for all modifications of the T-design with a shaft added to the support system, as well as for the model with a shaft and an extra shear wall added.

Note that the structural factor, $c_{s} c_{d}$, will have small variations with change of parameters within a typology. The structural factor affect the resulting wind load, but a new calculation of wind load for each modification is seen unnecessary, as the changes are small.

A brief check for the effect on including wind loads on the roof is also presented.

## Wind load on roof

The main model including wind load on the roof was checked. The deviation in deflections for wind in x -direction from the main model without wind load on the roof is presented in Table A.7.

Table A.7: Deflection with and without wind load on roof, RCR main

|  | Deflection $[\mathrm{mm}]$ |  |
| :--- | :--- | ---: |
| $\mathbf{x}$-dir |  |  |
| With wind on roof | 38.7 | $+0.26 \%$ |
| No wind on roof | 38.8 |  |

RCR: Main model, n8-shaft and n8d7-shear

Table A.8: Geometric properties, RCR main

|  | wing inner | 2.3 | 0.0 | 0.0 |

## Appendix B

## Acceleration

The acceleration of the building can be calculated from Equation (B.1) from Annex B in NS-EN 1994-1-4 [26].

$$
\begin{equation*}
a=\sigma_{a, x} \cdot k_{p} \tag{B.1}
\end{equation*}
$$

where
$\sigma_{a, x} \quad$ is the standard deviation of the wind induced acceleration
$k_{p} \quad$ is the peak velocity factor, with $v=n_{1, x}$

$$
\begin{equation*}
\sigma_{a, x}(z)=\frac{c_{f} \cdot \rho \cdot b \cdot I_{\nu}\left(z_{s}\right) \cdot v_{m}^{2}}{m_{e}} \cdot R \cdot K_{x} \cdot \phi_{1, x}(z) \tag{B.2}
\end{equation*}
$$

where
$c_{f} \quad$ is the force coefficient
$\rho \quad$ is the air density, $\rho=1.25 \mathrm{~kg} / \mathrm{m}^{3}$
$b \quad$ is the width of the structure
$I_{\nu}\left(z_{s}\right) \quad$ is the turbulence intensity, Equation (A.7)
$v_{m}\left(z_{s}\right) \quad$ is the mean wind velocity, Equation (A.8a), calculated with a return period of 2 years
$R \quad$ is the square root of the resonance response, Equation (A.13)
$K_{x} \quad$ is the non-dimensional coefficient
$m_{e} \quad$ is the along wind fundamental equivalent mass
$n_{1, x} \quad$ is the fundamental frequency of along wind vibration of the structure
$\Phi_{1, x}(z) \quad$ is the fundamental along wind modal shape
$z_{s} \quad$ is the reference height, $z_{s}=0.6 \cdot h \geq z_{\text {min }}$, see Figure A. 3
The force coefficient is dependent on the geometry of the building.

$$
\begin{equation*}
c_{f}=c_{f, 0} \cdot \Psi_{r} \cdot \Psi_{\lambda} \tag{B.3}
\end{equation*}
$$

where
$c_{f, 0} \quad$ is the force coefficient of rectangular sections with sharp corners, and dependent on the depth and with ratio. $c_{f, 0}$ is found in Figure 7.23 in NS-EN 1991-1-4
$\Psi_{r} \quad$ is the reduction factor for round corners, assuming sharp corners $\Psi_{r}=$ 1
$\Psi_{\lambda} \quad$ is the end-effect factor and a function of the solidity ratio $\varphi$ and the slenderness, see Section 7.6 in NS-EN 1991-1-4

Assuming $\Phi_{1, x}(z)=(z / h)^{\zeta}$ and $c_{0}=1, K_{x}$ can be approximated:

$$
\begin{equation*}
K_{x}=\frac{(2 \cdot \zeta+1) \cdot\left\{(\zeta+1) \cdot\left[\ln \left(\frac{z_{s}}{z_{0}}\right)+0.5\right]-1\right\}}{(\zeta+1)^{2} \cdot \ln \left(\frac{z_{s}}{z_{0}}\right)} \tag{B.4}
\end{equation*}
$$

$\zeta$ is the exponent of the mode shape
$z_{0}$ is the roughness length, $z_{0}=1$ for terrain category IV
For acceleration calculation the mean wind velocity, $v_{m}$, should be calculated with a return period of 1 year, and not 50 years as for the wind force [9]. Sine $p=1$ is not valid in the formula for the probability factor, 2 years is used as the return period.

$$
\begin{equation*}
c_{\text {prob }}=\left(\frac{1-K \cdot \ln (-\ln (1-p))}{1-K \cdot \ln (-\ln (0.98))}\right)^{n} \tag{B.5}
\end{equation*}
$$

where
$p \quad p=\frac{1}{\text { retur }}$, where retur $=2$
$K \quad$ is the shape parameter, $K=0.2$
$n \quad$ is the exponent, $n=0.5$

The peak factor $k_{p}$ :

$$
\begin{equation*}
k_{p}=\sqrt{2 \cdot \ln (v \cdot T)}+\frac{0.6}{\sqrt{2 \cdot \ln (v \cdot T)}} ; \quad k_{p} \geq 3 \tag{B.6}
\end{equation*}
$$

where
$v \quad$ is the up-crossing frequency, if $v<n_{1, x}, v=n_{1, x}$
$T \quad$ is the averaging time for the mean wind velocity, $\mathrm{T}=600$
The up-crossing frequency $v$ :

$$
\begin{equation*}
v=n_{1, x} \cdot \sqrt{\frac{R^{2}}{B^{2}+R^{2}}} ; \quad v \geq 0.08 \mathrm{~Hz} \tag{B.7}
\end{equation*}
$$

The equivalent mass, $m_{e}$, can be calculated in two different ways. Either with the exact integral i Equation (B.8), or in a simplified manner based on properties of the upper third of the building, shown in Equation (B.9).

$$
\begin{equation*}
m_{e}=\frac{\int_{0}^{l} m(s) \cdot \Phi^{2}(s) \mathrm{d} s}{\int_{0}^{l} \Phi^{2}(s) \mathrm{d} s} \tag{B.8}
\end{equation*}
$$

where
$m(s) \quad$ is the mass per unit length
$\Phi(s) \quad$ is the considered mode shape

$$
\begin{equation*}
m_{e}=\frac{m_{3}}{h_{3}} \tag{B.9}
\end{equation*}
$$

where
$m_{3} \quad$ is the average value of the mass over the upper third of the building
$h_{3} \quad$ is the height of the upper third of the building

## Appendix C

## Fire Design

Formulas for structural fire design are found in NS-EN 1995-1-1[27] and NS-EN 1995-1-2 [28].

## C. 1 Load actions

The load actions are gathered from Abaqus for each model and reduced by a factor 0.6 . The effect of actions:

$$
\begin{equation*}
E_{d, f i}=\eta_{f i} \cdot E_{d} \tag{C.1}
\end{equation*}
$$

where

$$
\begin{array}{ll}
E_{d} & \text { is the design effect of actions for normal temperature design, see limit } \\
\text { states from Section 2.4.5 } \\
\eta_{f i} & \text { is the reduction factor of design load in the fire situation, as a simpli- } \\
\text { fication } \eta_{f i}=0.6[28]
\end{array}
$$

## C. 2 Strength and stiffness

To verify mechanical resistance under fire loading, following formulas are used:

$$
\begin{equation*}
f_{d, f i}=k_{m o d, f i} \cdot \frac{f_{20}}{\gamma_{M, f i}} \tag{C.2}
\end{equation*}
$$

$$
\begin{equation*}
S_{d, f i}=k_{m o d, f i} \cdot \frac{S_{20}}{\gamma_{M, f i}} \tag{С.3}
\end{equation*}
$$

where
$f_{d, f i} \quad$ is the design strength in fire
$S_{d, f i} \quad$ is the design stiffness property, modulus of elasticity, $E_{d, f i}$, or shear modulus, $G_{d, f i}$
$f_{20} \quad$ is the $20 \%$ fractile of the strength property at normal temperature
$S_{20} \quad$ is the $20 \%$ fractile of the stiffness property at normal temperature
$k_{\text {mod, } f i} \quad$ is the modification factor for fire, $k_{\text {mod, } f i}=1$
$\gamma_{M, f i}$ is the partial safety factor, $\gamma_{M, f i}=1$

$$
\begin{equation*}
f_{20}=k_{f l} \cdot f_{k} \tag{C.4}
\end{equation*}
$$

$$
\begin{equation*}
S_{20}=k_{f l} \cdot S_{05} \tag{C.5}
\end{equation*}
$$

where
$S_{05} \quad$ is the $5 \%$ fractile of the stiffness property at normal temperature
$k_{f l} \quad$ for glue laminated timber $k_{f l}=1.15$
$\gamma_{M, f i} \quad$ is the partial safety factor, $\gamma_{M, f i}=1$
Table C. 1 gives and overview over the characteristic strength and stiffness properties [22] and the calculated strength and stiffness properties for fire design.

Table C.1: Strength and stiffness properties for GL30c

|  | Characteristic | $\left[\mathrm{N} / \mathrm{mm}^{2}\right]$ | Design in fire | $\left[\mathrm{N} / \mathrm{mm}^{2}\right]$ |
| :--- | :--- | ---: | :--- | ---: |
| Bending strength | $f_{m, g, k}$ | 30.0 | $f_{m, f i}$ | 34.500 |
| Tensile strength | $f_{t, 0, g, k}$ | 19.5 | $f_{t, 0, f i}$ | 22.425 |
|  | $f_{t, 90, g, k}$ | 0.5 | $f_{t, 90, f i}$ | 0.575 |
| Compression strength | $f_{c, 0, g, k}$ | 24.5 | $f_{c, 0, f i}$ | 28.175 |
|  | $f_{c, 90, g, k}$ | 2.5 | $f_{c, 90, f i}$ | 2.875 |
| Shear strength | $f_{v, g, k}$ | 3.5 | $f_{v, f i}$ | 4.025 |
| Modulus of elasticity | $E_{0, g, 05}$ | 10800.0 | $E_{0, f i}$ | 12420.000 |

## C. 3 Capacity of cross section

The remaining effective cross section are calculated by using Equation (2.9) in Section 2.6. When exposed to fire on only one sides, the remaining dimensions of the cross section are:

$$
\begin{aligned}
& h_{e f}=h-d_{e f} \\
& b_{e f}=b-d_{e f}
\end{aligned}
$$

where
$h \quad$ is the initial height of the cross section
$b \quad$ is the initial width of the cross section
$d_{e f} \quad$ is the charred and in-effective part of the cross section
Equations from NS-EN 1995-1-1 are used to calculate the capacity of the cross section when exposed to the fire load [27]. Figure C. 1 defines the directions used for the column cross section.

Figure C.1: Definition of $y$ - and $z$-direction for the column cross section

## C.3.1 Shear capacity

$$
\begin{align*}
\frac{\tau_{d, y, f i}}{f_{v, f i}} & \leq 1  \tag{C.7a}\\
\frac{\tau_{d, z, f i}}{f_{v, f i}} & \leq 1 \tag{C.7b}
\end{align*}
$$

where

$$
\begin{aligned}
& \tau_{d, f i}=\frac{3}{2} \cdot \frac{V_{d}}{b_{e f, c r} \cdot h_{e f}} \\
& b_{e f, c r}=k_{c r} \cdot b_{e f}
\end{aligned}
$$

$\tau_{d, f i} \quad$ is the design shear stress
$V_{d, f i} \quad$ is the design shear load
$b_{e f, c r} \quad$ is the effective width to account for fracture in the cross sections
$h_{e f} \quad$ is the effective height of the cross sections
$k_{c r} \quad$ for glulam $k_{c r}=0.67$

## C.3.2 Combined bending and axial tension

$$
\begin{align*}
& \frac{\sigma_{t, 0, f i}}{f_{t, 0, f i}}+\frac{\sigma_{m, y, f i}}{f_{m, y, f i}}+k_{m} \cdot \frac{\sigma_{m, z, f i}}{f_{m, z, f i}} \leq 1  \tag{C.9a}\\
& \frac{\sigma_{t, 0, f i}}{f_{t, 0, f i}}+k_{m} \cdot \frac{\sigma_{m, y, f i}}{f_{m, y, f i}}+\frac{\sigma_{m, z, f i}}{f_{m, z, f i}} \leq 1 \tag{C.9b}
\end{align*}
$$

where

$$
k_{m} \quad \text { for rectangular cross sections } k_{m}=0.7
$$

The bending stresses and axial tension are calculated with the reduced forces and effective cross section.

$$
\begin{aligned}
\sigma_{c, f i} & =\frac{N_{R d, f i}}{A_{e f}} \\
\sigma_{m, y, f i} & =\frac{M_{R d, y, f i}}{W_{y, e f}} \\
\sigma_{m, z, f i} & =\frac{M_{R d, z, f i}}{W_{z, e f}}
\end{aligned}
$$

## C.3.3 Combined bending, axial compression and buckling

$$
\begin{align*}
\frac{\sigma_{c, 0, f i}}{k_{c, y} \cdot f_{c, 0, f i}}+\frac{\sigma_{m, y, f i}}{f_{m, y, f i}}+k_{m} \cdot \frac{\sigma_{m, z, f i}}{f_{m, z, f i}} & \leq 1  \tag{C.11a}\\
\frac{\sigma_{c, 0, f i}}{k_{c, z} \cdot f_{c, 0, f i}}+k_{m} \cdot \frac{\sigma_{m, y, f i}}{f_{m, y, f i}}+\frac{\sigma_{m, z, f i}}{f_{m, z, f i}} & \leq 1 \tag{C.11b}
\end{align*}
$$

where

$$
k_{m} \quad \text { for rectangular cross sections } k_{m}=0.7
$$

Formulas for calculating buckling. Calculate for y -axis and z -axis:

$$
\begin{align*}
k_{c} & =\frac{1}{k+\sqrt{k^{2}-\lambda_{r e l}^{2}}}  \tag{C.12a}\\
k & =0.5 \cdot\left(1+\beta_{c} \cdot\left(\lambda_{r e l}-0.3\right)+\lambda_{r e l}^{2}\right) \tag{C.12b}
\end{align*}
$$

$$
\begin{align*}
\lambda_{r e l} & =\frac{\lambda}{\pi} \cdot \sqrt{\frac{f_{c, 0, k}}{E_{0.05}}}  \tag{C.13a}\\
\lambda & =\frac{l_{e f}}{i} \tag{C.13b}
\end{align*}
$$

where
$l_{e f} \quad$ is the buckling length, conservatively assuming $l_{e f}=3 \mathrm{~m}$, which is the height of one storey. This assumption is conservative ${ }^{1}$
$i \quad i=\frac{h_{e f}}{\sqrt{12}}, i=\frac{b_{e f}}{\sqrt{12}}$, where $h_{e f}$ and $b_{e f}$ are the dimensions of the effective cross section
$\beta_{c} \quad$ for glulam $\beta_{c}=0.1$

[^11]
## C.3.4 Lateral torsional instability

$$
\begin{equation*}
\left(\frac{\sigma_{m, y, f i}}{k_{c r i t} \cdot f_{m, y, f i}}\right)^{2}+\frac{\sigma_{c, 0, f i}}{k_{c, z} \cdot f_{c, 0, f i}} \leq 1 \tag{C.14}
\end{equation*}
$$

where
$k_{\text {crit }}$ is a factor which takes into account the reduced bending strength due
to lateral buckling

$$
k_{\text {crit }}= \begin{cases}1.0 & \text { for } \lambda_{r e l, m} \leq 0.75  \tag{C.15}\\ 1.56-0.75 \cdot \lambda_{\text {rel }, m} & \text { for } 0.75<\lambda_{r e l, m} \leq 1.4 \\ \frac{1.0}{\lambda_{r e l, m}^{2}} & \text { for } 1.4<\lambda_{r e l, m}\end{cases}
$$

$\lambda_{\text {rel, } m}$ is the relative slenderness, and is calculated in accordance to Equation (C.16).

$$
\begin{equation*}
\lambda_{r e l, m}=\sqrt{\frac{f_{m, y, f i}}{\sigma_{m, c r i t}}} \tag{C.16}
\end{equation*}
$$

where
$\sigma_{m, c r i t} \quad$ is the critical bending stress

$$
\begin{equation*}
\sigma_{m, c r i t}=\frac{0.78 \cdot b_{f i}^{2}}{h_{f i} \cdot l_{e f}} \cdot E_{0.05} \tag{C.17}
\end{equation*}
$$

$b_{f i} \quad$ is the effective cross sectional width due to fire
$h_{f i} \quad$ is the effective cross sectional height due to fire
$l_{e f} \quad$ is the effective lateral buckling length, $l_{e f}=3 \mathrm{~m}^{2}$

[^12]
## Control of lateral buckling

Lateral buckling may occurs when the second moment of inertia is considerable larger about the strong axis than the weak axis, making slender columns critical. For all increased cross sections in this thesis, $\lambda_{\text {rel,m }}$ is less than 0.75 , and lateral buckling will then not occur. Table C. 2 list $k_{\text {crit }}$ and $\lambda_{\text {rel,m }}$ for the main models and the most slender column for a increased cross section.

Table C.2: $k_{c r i t}$ and $\lambda_{r e l, m}$ for different cross sections

| Effective cross section [mm] | $k_{\text {crit }}$ | $\lambda_{\text {rel,m }}$ |
| :--- | :---: | :---: |
| $70 \times 380$ (T-design, outer corner column) | 0.85 | 0.94 |
| $70 \times 310$ (RCR, corridor column) | 0.92 | 0.85 |
| $140 \times 605$ (T-design, outer corner column) | 1.00 | 0.60 |

## C. 4 Resulting fire design

The tables not listed in Chapter 4 are presented here, from Table C. 3 to C.8. In this section the resulting fire loads are listed, together with the calculated utilisation of the cross sections.

## C.4.1 Design: Room Cooridor Room

## C.4.2 Variation of storeys

Six storeys.
Table C.3: Fire design loads, six storeys n6d6, Combination $3+4$

## Appendix D

## Slab Partition

Since the connection properties between the slabs are unknown, they are modelled as a partition with properties resembling $1 / 10$ of the bending stiffness of the slab about the strong axis. The partition is modelled as an isotropic material and the poission ratio is set to $v=0.3$.

The bending stiffness for a plate:

$$
\begin{equation*}
D=\frac{E t^{3}}{12 \cdot\left(1-v^{2}\right)} \tag{D.1}
\end{equation*}
$$

For the slab $t=350 \mathrm{~mm}$ and $E_{1}=15000 \mathrm{~N} / \mathrm{m}^{2}$ and $v_{12}=0.6$ in the longitudinal direction. The resulting stiffness $D=8.374 \cdot 10^{10} \mathrm{Nmm}$.

The bending stiffness for a beam:

$$
\begin{equation*}
E I=\frac{E \cdot b h^{3}}{12} \tag{D.2}
\end{equation*}
$$

The dimensions for the partition are set to: $b=100 \mathrm{~mm}$ and $h=350 \mathrm{~mm}$.
$E I \approx 1 / 10 \cdot D$, resulting elastic modulus for the partition $E=23.4 \mathrm{MPa}$ rounded up to be $E=30 \mathrm{MPa}$.
