SINTEF Proceedings
SINTEF Proceedings is a serial publication for peer-reviewed conference proceedings on a variety of scientific topics.
The processes of peer-reviewing of papers published in SINTEF Proceedings are administered by the conference organizers and proceedings editors. Detailed procedures will vary according to custom and practice in each scientific community.
PREFACE

This book contains all manuscripts approved by the reviewers and the organizing committee of the 12th International Conference on Computational Fluid Dynamics in the Oil & Gas, Metallurgical and Process Industries. The conference was hosted by SINTEF in Trondheim in May/June 2017 and is also known as CFD2017 for short. The conference series was initiated by CSIRO and Phil Schwarz in 1997. So far the conference has been alternating between CSIRO in Melbourne and SINTEF in Trondheim. The conferences focuses on the application of CFD in the oil and gas industries, metal production, mineral processing, power generation, chemicals and other process industries. In addition pragmatic modelling concepts and bio-mechanical applications have become an important part of the conference. The papers in this book demonstrate the current progress in applied CFD.

The conference papers undergo a review process involving two experts. Only papers accepted by the reviewers are included in the proceedings. 108 contributions were presented at the conference together with six keynote presentations. A majority of these contributions are presented by their manuscript in this collection (a few were granted to present without an accompanying manuscript).

The organizing committee would like to thank everyone who has helped with review of manuscripts, all those who helped to promote the conference and all authors who have submitted scientific contributions. We are also grateful for the support from the conference sponsors: ANSYS, SFI Metal Production and NanoSim.

ABSTRACT
The Si-Mn alloy process production in submerged arc furnaces (SAF) is investigated. The aim of the studies currently in progress is an enhancement of the knowledge about the key reactions and the mass transport phenomenon related to the metal production. Some small scale experiments on raw materials and bigger pilot scale experiments are done to understand local kinetic and its extension to real condition production furnaces. As it is impossible to observe what is happening in the core of the furnace during operation, excavation of the pilot scale furnace are realised after operations. Based on bibliographical description of similar processes, observations and species analyses after excavation, a numerical simulation is currently in development to test the hypothesis formulated about the internal behaviour of the furnace. As it is difficult to model the complex entire furnace, the work presented here is focusing on what are the phenomenas inside the coke bed, in the dripping zone where the slags flow around the carbon particles before reaching the bottom of the furnace. The thrickling of the slags across the coke bed can be evaluated by a simulation of the droplets finding their path by gravity through the packing of carbon particles. This study has to be very local in space and time, but can give some useful informations such as velocities and drag force. At a larger scale (ie furnace scale), the coke bed particles are modelled by a granular phase in an eulerian-eulerian representation where the slag phase flow interact in the same way as in the local study. The slag is found to flow across the coke bed under the form of droplets of a maximum diameter of 10mm. The apparent velocity of the fluid is about 0.12 m/s. However the residence time of the droplets is longer due to the liquid trapped along the coke bed.

Keywords: Packed bed, Granular flow, Free surface flow, Multi-phase mass transfer, Multiscale.

INTRODUCTION
In the steel industry, manganese is an important element needed in order to produce specific grades of steel, ranging from materials having a great toughness, a high strength or containing low carbon. Manganese is added into the steel production furnace in the form of alloys and mainly ferroalloys. Silico-manganese, also called SiMn is another alloy which is privileged in the production of silicon and manganese containing steel.

The major part of SiMn is produced in submerged arc furnace (SAF) by carbothermic reduction of oxidic raw materials. An experimental effort has been conducted these last years at NTNU, operating a pilot scale SAF to investigate the parameters limiting the conversion of slag into metal alloy. Currently about 35 % of the mass is tapped from the production furnace as a metal, leaving the 65% remaining in a slag form.

To facilitate the understanding of the furnace, a modeling effort of the furnace is conducted in order to give different scenarios conducting to the conversion of slag into metal. Hypothesis has to be made to describe the furnace, and, to reduce the complexity of the problem, the whole problem has been split into more elementary part.

This paper is focusing on the modeling strategy used to depict one part, identified as the dripping part of the furnace.
At least 4 phases have to be taken into account that are challenging modeling where some choices have to be done. The existence of different zones inside the furnace lead to phenomena both in a mathematical way and due to the chemical reactions. The complexity of the interdependency of dynamics, turbulent hydrodynamics, heat radiation and chemical reactions. The process involves various different physical phenomena which are coupled together such as electricity, thermodynamics, turbulent hydrodynamics, heat radiation and chemical reactions. The complexity of the interdependency of these phenomena both in a mathematical way and due to the existence of different zones inside the furnace lead to challenging modeling where some choices have to be done.

**Phases** At least 4 phases have to be taken into account that is the gas phase, the solid phase and two liquid phases. The oxides form the liquid slag phase, whereas the reduced oxides are combined together into another liquid phase which is the metal phase. The pre-reduction zone is mainly constituted of solid and gas whereas in the reduction zone, the two liquids are flowing through a bed of solid particles.

**Species** The number of species present can be quite large due to the wide variety of ore materials used. In those materials some elements participate only in the slag phase(CaO,MgO,BaO,Al2O3), as they seem not to be involved into the reacting system of metal production. The solid material are mainly Mn3O4, SiO2, and the carbon represented as coke. The fluid species can be classified in two types that is the oxides and the metallic compounds. The slag components taking part of the reaction are mainly SiO2 and MnO whereas the metallic component are by order of importance Mn, Fe and Si. The gas phase is composed of CO and CO2, but only CO is present into the whole furnace. In this paper we focus on the way the melting ores are dripping on carbon particles.

**DATAS AVAILABLE TO PROCESS THE MODELING.**

Due to the temperature, the size, and the opacity of the system, it is difficult to monitor internal parameters such as the temperature, the flow rate, or the reduction rate in the furnace. The data available during a run are mostly external parameters that is the power supplied to the installation and the variation of resistance measured in between the electrodes, the quantity of molten slag and metal collected every 30 min, the temperature of the tapped liquid and the analysis of this liquid components after operations. At the end of the operations the furnace is cooled down and the void areas are filled with epoxy. A slice along the diameter of the furnace is realised. This slice, called the excavation plate, gives us a picture of the furnace at the instant when the electrical power is shutdown. The informations extracted from it can help us to understand the internal process during operations. The hypothesis made is that no reduction happen during the cooling process as not enough power is supplied to continue the reduction. From the excavation of the furnace some informations about the solid phase packing can be extracted, as well as the composition of some phases remaining. According to these excavations, it seems that 90% of the reduction happen on a thin layer situated at the top of the reduction zone, at the interface with the pre-reduction zone, where the reacting ores, already liquid are reduced. The 10% remaining reduction should happen in the coke bed by dripping down through it.

**COKE BED, THE DRIPPING ZONE**

As the phenomenons explaining that most of the reduction operations happen on the top of the coke bed are not yet well identified and just hypothesis, it is difficult to model the entire coke bed as a whole. Indeed the slag in liquid state has to stay long enough on the top of the coke bed to be reduced without flowing in the down part of the coke bed.
To decouple the problem, we focus on the way the liquid slag flow through the coke bed (see figure 1). This zone is referred to the dripping zone. It is the zone where the slag flow by gravity around the carbon particles. The description we depict now is similar to the one observed in the blast furnace where the dripping zone is described as a zone of great importance to the mass transfer of elements (Husslage et al., 2005).

To study this zone we are using two different numerical models involving two different scales:

- one local model where the interstitial space between carbon particles is meshed, and where the interface of the flowing fluid slag is tracked with the help of the Volume of Fluid method
- one global model where the phases fractions are tracked in each cells with the Euler-Euler method. In this model, the cells are bigger than the inter-poral space and the whole dripping zone is modeled.

In the dripping zone the temperature is assumed to be maintained at a value of about 1873 K. It is the temperature measured of the tapped metal, and just above the temperature of reduction of the ores.

THE TWO SCALES MODEL

The local model

This part of the calculations referred to the local model are done in order to give a representation about the intensity and the configuration of the dripping slag into the coke bed.

We consider a 2D box representing some carbon particles digitized from the real geometry (figure 2). In this box only the poral space around the carbon particles is meshed, using the snappyHexMesh tool of OpenFoam 4.1 (OF4.1).

The method used is the Volume Of Fluid method which solve all the phases with one set of conservation equations. The solver is the interFlow solver based on interFoam version of OF-4.1.

In this solver, the interface reconstruction algorithm used is the recent isoAdvector algorithm (Roenby et al., 2016), which oppositely to MULES, use geometrical interface reconstruction and advection instead of algebraic interface compression. This algorithm has been found to be more accurate in interface advection and reducing splashing of small parts of the volume fraction out of the main fluid flow. The performance of the algorithm is also very good in comparison to others geometrical reconstruction algorithm. Additionally the advection of the interface is almost not affected by the type and shape of cell used.

The solver is modified to introduce the gravity field into the momentum equation instead of the pressure equation, to avoid problems due to the non periodicity of the pressure field. The average slag velocity in the box is calculated with the velocity of the liquid phase along the dripping path of the slag. The volume of fluid reported divided by the height of the box and the final velocity, gives us the flow rate obtained when the slag reaches the bottom of the coke bed.

The goal of this calculation is to depict the behaviour of the slag when the flowrate calculated at the bottom of the coke bed is similar to the one deduced from the quantity of liquid obtained from each tapping of the pilot-scale experiment. This calculation is done iteratively by correcting the quantity of liquid introduced and the size of the simulation box until reaching some result in accordance with the experimental quantities obtained.

The hypothesis done during the calculation is that the slags are flowing homogeneously in the whole dripping zone and that the flow rate stay constant during all the process. The thickness of the droplets is estimated as being the average of the diameter of the flowing droplets considered. This study can be completed by taking into account the variation of the viscosity, surface tension, density and contact angle along the path, due to composition variation. As it is still a bit difficult to obtain the correct informations into both spatial variations of composition and properties evolutions related to these composition variation, the properties have been, in this attempt, kept constant.

This averaged velocity of the dripping slag has been reinterpreted in terms of drag coefficient of the coke bed:

$$
F_{\text{drag}} = \alpha_s \rho_s (u_p - u_s) K_{p-s} + \alpha_s \rho_s (u_p - u_s) K_{s-p} - \alpha_s \rho_s g
$$

If we consider that there is no drag interaction between the gas and the slag phase and that the solid particles are not moving, we can then estimate the value of $K_{p-s}$ with the expression $K_{p-s} = g/\mu_s$.

The physical properties used to calculate the flow are based on the composition of the slag tapped after experiment. These properties are summarized in table 2 for an average slag composition obtained over several tapping given in 1.

The global model

The Euler-Euler model of Fluent 17.2 is used to represent the dripping part of the whole furnace. This model offers the possibility to study a process on a large scale geometry. This model has been used to simulate several complex processes involving several phases and reactions. In metal production it has been used to simulate the trends of the silicon production process in an industrial configuration (Darmana et al., 2012). In this model particle, liquids and gas phases are present in each cell. The phase fraction of the phases are tracked as well as their averaged velocity and temperature in each cell.

Boundary conditions

The fluid is entering the top part of the coke bed near the electrode, and the fluid is free to leave the coke bed (pressure outlet conditions) on both the lower part and the upper part of the coke bed (figure 3). The velocity inlet conditions are set in a way to respect the global flowrate of the experiment. The velocity is set at a similar value as the main value wanted into the coke bed, and the inlet phase fraction is adapted to this value.

Solid phase

The granular model is used to model the coke particles. The coke bed is represented as a packed bed with no velocity. The solid phase fraction is taken as the same as the one used in the local model (0.39). The size of the particles is also taken as representative of the coke bed (0.01 m).

Liquid phase

The main parameter of the liquid phase is the size of the droplets flowing through the solid phase. The droplet size is assumed to be homogeneous in the whole furnace and the value is estimated from the calculations of the local model. The phase fraction in the domain is calculated from the imposed boundary conditions.

Gas phase

The gas phase is the main or continuous phase which means that its phase fraction is calculated with the space not occupied by the other phases following \( \alpha_{\text{solid}} + \alpha_{\text{liquid}} + \alpha_{\text{gas}} = 1 \).

Geometry

The geometry boundary are sketched from:

1. The walls of the furnace for the down and side boundary
2. The shape of the reduction zone determined from the excavation plate of the furnace.

The shape of the reduction zone can be located as the fictive boundary separating the zones with different solid composition. On the upper part a mix of solid coke and ore particles can be observed whereas on the lower part there is just solid coke remaining. The mesh generated with the Delaunay algorithm for quad (Remacle et al., 2010) of the GMSH utility, is represented on figure 3.

Drag coefficient

For the calculations of the drag coefficient between fluids the Schiller-Naumann correlation is used. For the drag interaction between the liquid and the solid, the \( K_{\text{p-g}} \) coefficient calculated previously and adapted to the dimensions required by the equation solved by Fluent (\( \text{kg.m}^{-1}.\text{s}^{-1} \)) is used.

RESULTS

Local model

The VOF model gives us several informations about the distribution of the droplets into the coke bed. First, small droplets (diameter < 9mm) will flow quickly in places where the pore size is superior to their size. Depending on their velocity these droplets will go through smaller interpores. If the smaller interpore zone is smaller than the droplet diameter, and its inertia is not sufficient to cross the obstacle, then the droplet will get stuck. These droplets may fragment into smaller droplets when they impact a bigger particle with a high velocity (0.5 m/s), but usually due to the high surface tension and the friction along the coke bed, these droplets rarely split. The high density (3 times higher than water), and the relatively low dynamic viscosity (comparable to olive oil) permit the slag phase to flow easily into the coke bed. Oppositely, the contact angle and the high surface tension oppose a resistance when it comes to zone with smaller pore dimensions.

Big droplets (diameter >10mm) split in smaller droplets during their trickling path through the coke bed. The dynamic of the obtained droplets depends on the size of these droplets. As long as the smallest pores between particles is not filled with slag, the droplets will partially attach to the carbon particles which leads to a non steady flow rate, and a residence time of a droplet which vary at the beginning of the simulation. As these poral spaces of the coke bed are filled
with slag, we have a continuous process which begin, one droplet pushing the precedent droplet out to feel the cavity or to extract the totality of the fluid, releasing each time new droplets. The size and the dynamic of the new droplet depend on the quantity of liquid extracted from the cavity.

In this pseudo stationary regime the movement of fluid is estimated to be around 0.12 m/s with velocities ranging from 0 m/s for the droplets trapped into the coke bed up to about 0.5 m/s during (free fall of some small droplets). The velocity of the droplets vary depending on how many filled cavities are met along the droplet path inside the coke bed. If we consider that the liquid pushed out of the cavity is the continuity of the one pushing the liquid then the velocity of one bubble of a diameter of 9 mm is about 0.12 m/s. The final size of the droplet at the bottom of the furnace does not depend directly of the size of the initial droplet but also of the quantity of liquid trapped into the pores. If the size of droplets stemming from the top of the coke bed is stationary then the size of a droplet trapped is about the same size and the size of the bubble released is also approximatively the same.

The wetting of the particles is a key parameter to determine the contact area between the slag and the solid particles. It depends on the physical properties of the fluid, in particular the contact angle, but also on the geometry of the particles and the interstitial space where the droplets are trapped. The scarcity of the droplets flowing through the coke bed and the high value of the contact angle explain that only a few part of the coke surface is wet by the slag in the dripping zone.

**Global model**

Introducing the correct order of magnitude of the particle size, coke bed void fraction and drag coefficient permit to simulate an averaged situation which is representative of our local simulation. The droplets of the predetermined size (4 mm in our simulations) flow in a coke bed at the approximate velocity of 0.1 m/s. This lead to a distribution of the phase fraction given by the calculation on figure 5. This model as such does not give more informations as it reproduces in a modeled way the results obtained with the local model. The idea behind the use of this model is to add an energy balance calculation in the system by choosing the appropriate boundary conditions, energy sources and energy consumption inside the coke bed. This needs an accurate description of the thermo-physical properties of the system, electrical power released and of the kinetic of the reaction system. A first attempt has been made in this direction using the simplified system

\[
\text{MnO}_{\text{slag}} + C_{\text{solid}} \rightarrow \text{Mn}_{\text{metal}} + \text{CO}_{\text{gas}}
\]

**Figure 4:** 3-6 mm droplets flowing along coke particles

**Figure 5:** Velocity and phase fraction of the slag phase dripping into the coke bed

**Figure 6:** Reaction rate in the coke bed volume (kmol/m$^3$.s$^{-1}$)

In the figure 6 we can see the calculated reaction rate of our implementation. The results are homogeneous on most of the part of the furnace, and a bit higher on the top zone of the furnace where the fluid is slower. It is not yet a goal in this paper to reproduce the real reduction behavior of the furnace, but to present the modeling strategy used to help understanding the furnace operations by adapting the input datas of the model to the observations.

**DISCUSSION**

This modeling answers some questions:

1. The fluidity of the slag in a fully liquid state cannot explain that 90% of the reduction happen at the top of the
coke bed. Another explanation has to be found to explain the residence time of the slags on this part of the furnace.

2. The slag is not flowing down through the coke bed as a continuous flow but by succession of droplets coming from the reduction zone at the top of the coke bed.

3. The chemical composition of these droplets is not just evolving by reaction along the path imposed to them by the gravity, which would result in very few reduction as their residence time would be small.

Instead, some droplets stay at some places into the coke bed until another droplet push it down. There is certainly a permanent renewal of the chemical concentration of these droplets which are trapped. So it can be considered that a real droplet has an average residence time in the coke bed which is superior to the impression it gives when flowing from cavity to cavity. In addition the renewal of the droplet may depend on the position in the coke bed. On the peripheral part of the main dripping zone, some droplets are renewed less often than in the main flow leading probably to a less important reduction rate. In 3D also there are more accessible places for a droplet to stay before being pushed by another one. In addition, the modification of the chemical composition of the droplets modifies the physical properties. The trajectories of these droplets are very sensible to the physical properties due to the cominaison of variation of properties as the contact angle, the surface tension and the viscosity. The trajectories of the flow will probably defer from droplet to droplet leading to an exploration of the whole geometry of the droplets should be greater than the apparent velocity of the fluid to take into account that the droplets stay often trapped into the coke-bed. These effects can be taken into account into the big scale model by introducing the appropriate drag coefficient. This model can be used to simulate the reductions reaction and validate a thermal balance of the coke bed zone.
