Abstract: Dynamic Positioning (DP) of ships is a control mode that seeks to maintain a specific position (stationkeeping) or perform low-speed maneuvers. In this paper, a static Neural Network (NN) is proposed for control allocation of an over-actuated ship. The thruster force commands from a motion controller into individual thruster commands. A standard Proportional Integral Derivative (PID) controller, using wave-filtered position and heading measurements, is implemented as motion controller for each Degree Of Freedom (DOF) of the ship. For a DP application the controllable DOFs are the translational motion in surge and sway directions, as well as the rotation about its up/down axis. Simulation tests were performed to verify the feasibility of this approach.

Keywords: PID controllers, Neural-network models, Dynamic positioning, Control allocation

1. INTRODUCTION

Ships that are involved in safety-critical operations related to drilling, cargo-transfer, subsea crane operations and pipe-laying typically have an extended actuator setup to allow for redundancy in case of system errors. During such operations the vessel is required to control its position and heading. This operational mode is known as Dynamic Positioning (DP), which performs stationkeeping or low-speed maneuvering. In terms of the degrees of freedom (DOF) of the vessel, DP normally controls the surge (longitudinal), sway (lateral) and yaw (rotation about the up/down axis) simultaneously. Conventional ships use either tunnel thrusters, azimuth thrusters or main thrusters for thrust generation.

In order to perform DP operations a modular approach to motion control is often applied (Johansen and Fossen (2013)). A top-level motion controller converts the error between the desired state and the actual state of the ship, into a generalized force vector in surge/sway direction and moment about the yaw axis. Then a control allocation module distributes that force vector into individual thruster commands to fulfill the requirements of the motion controller.

Historically, optimization-based control allocation techniques have dominated. This allows for flexibility in terms of optimization goal (and sub-goals), motivating advances in minimum power schemes and minimization of actuator wear. Lindegaard and Fossen (2003) exploited the operation of a rudder for lateral thrust to derive an energy-efficient thrust allocation algorithm for low speed operations. An explicit two-step solution was suggested to calculate a feasible thrust vector, \( u \). The approach was limited to one rudder at a time. Their algorithm was extended by Johansen et al. (2008) to allow any number of rudders. Magnitude and rate constraints were also accounted for. Perez and Donaire (2009) handled both magnitude constraints and rate constraints in the top-level motion controller by an anti-windup controller. By constraining the virtual control vector from the motion controller, they could perform unconstrained control allocation which was posed as an optimization problem. The solution to this unconstrained control allocation may be found in (Fossen (2011)).

Sordalen (1997) used filtering techniques to tackle the problem of azimuth angle rate constraints for rotatable thrusters. Without this constraint consideration, a singular thruster configuration may occur when rotatable thrusters are used actively. The result is failing to meet the control commands of the control law.

An adaptive genetic algorithm was used to solve the thrust allocation problem in (Zhao et al. (2010)). A fitness function was constructed based on an objective function with constraints. They considered thrust allocation for a semi-submersible rig using rotatable thrusters. Constraints considered were thruster force limits, its change rate,
angular rate of thrusters and respective forbidden azimuth angles. Bui and Kim (2011) presented a control allocation scheme that involved the use of external thrust providers in the form of autonomous tugboats for ship berthing application. A constrained optimization problem was used, which they solved using a redistributed pseudo-inverse algorithm.

Chen and Jiang (2012) transformed the constrained allocation task into a convex quadratic programming problem for constrained control allocation. To solve this they applied a recurrent neural network. A neural network control algorithm was applied in (Zhang et al. (2017)) to overcome actuator gain uncertainties and to compensate for un-modelled environmental disturbances. The algorithm was tested in a simulator using six thrusters, where one of them was rotatable. Realistic environmental disturbances were applied in the simulation test.

Except for the approach described by Zhang et al. (2017), the methods described above require knowledge about the command-to-force relationship of each thruster.

Within the aerospace industry, control allocation has also received significant attention. An overview of methods used within this domain is given in Oppenheimer et al. (2006), while an evaluation of methods is given in Bodson (2002).

In this article we propose to use a neural network to obtain the mapping between the virtual generalized force, commanded by the motion controller, and the individual thruster command. It will consider thruster rate constraints as well as limiting the maximum and minimum commands of the thrusters (magnitude constraint) for non-rotatable thrusters. Manual operation of the thrusters is used to generate the training data. Sequentially, each thruster was put through its entire operational range by first ordering a maximum command. Then, when maximum was reached, a minimum command was issued. In addition to reaching maximum/minimum thruster command values, this commands the maximum change rate as well. In this paper, no explicit support for relative weighting between thrusters exist. To achieve this, the designer would have to supply the network with a training set that reflected the desired weighting. This could be a restricted operational range for the main thrusters, resulting in lower force output by those thrusters. Two assumptions were made:

- The forces and moments imparted by each thruster on the vessel are measurable.
- The command-to-force relation gathered in the test set for calm seas is representative for command-to-force relations in all other sea states.

To validate the scheme, and for collecting training data for the NN allocation mapping, a simulated vessel will be used.

2. CONTROL SCHEME

As noted by Johansen and Fossen (2013) there typically exists a hierarchy in the control system for over-actuated mechanical systems. This hierarchy allows for a modular design where each module is self-contained. Figure 1 gives an overview of the complete system used in this paper. \( \tau_c \) is the commanded virtual force and moment given in the vessel frame of reference. \( u \) is the vector of individual control commands. \( \tau \) is the individual horizontal plane forces imparted on the virtual ship by the thrusters. \( \tau_{env} \) are the forces acting on the vessel through environmental disturbances. Included in the PID Motion controller module (section 2.2) is a wave filter, which will be described in section 2.1. The NN control allocation module of figure 1 contains both an initial training algorithm and a forward calculation of the control vector \( u \). The latter operation is executed at each step of the complete system. An update rate of 20 Hz was used. The output of the control allocation module will be input directly to each thruster.

2.1 Wave filter

Prior to sending the relevant measurements to a control system it is customary to filter the signals to avoid compensating for high-frequency wave-induced motion (Fossen and Perez (2009)). This process is therefore often referred to as wave-filtering and is a necessary step to reduce wear and tear on actuators. Several tools can be used for this purpose including low-pass filters, Kalman filters and observers (Fossen (2011)). Low-pass filters are utilized in this stage. Although it has limited effect due to the phase lag incurred, they do not require prior knowledge of either vessel dynamics or the impact of environmental forces on the vessel.

2.2 PID motion controller

A standard PID controller was used to obtain the virtual forces necessary to converge to a given desired state. The need for integral action is evident when considering the drift force exerted on the vessel by wind, low frequency wave drift forces and ocean currents. Position measurements were given in the local North East Down (NED) frame. This made it necessary to rotate the position in the horizontal plane in order to provide error metrics aligned with the coordinate frame of the vessel. For DP operation, we define the state vector in the NED reference frame as \([N, E, \psi]^T\) and \([X, Y, \psi]^T\) for the state vector in the vessel reference frame. \(\psi_d\) is the desired heading angle of the vessel. Figure 2 shows the X and Y axis of the vessel-bound state vector.

Equation 1 yields the error signal which will act as input to the PID motion controller.

\[
\begin{bmatrix}
X_{err} \\
Y_{err} \\
\psi_{err}
\end{bmatrix} = R^{-1}(\psi)
\begin{bmatrix}
N_d \\
E_d \\
\psi_d
\end{bmatrix} -
\begin{bmatrix}
N \\
E \\
\psi
\end{bmatrix}
\]  

(1)

Obtaining the virtual control vector is achieved by applying a PID controller for each DOF represented in the vessel fixed state vector.

\[
\begin{bmatrix}
F_x \\
F_y \\
M_{\psi}
\end{bmatrix} =
\begin{bmatrix}
PID(X_{err}) \\
PID(Y_{err}) \\
PID(\psi_{err})
\end{bmatrix}
\]  

(2)

where \( PID(e) = K_p \ast (e + 1/T_i \ast \int_0^t e) + T_d \ast \dot{e} \) and \( K_p, T_i \) and \( T_d \) are parameters of the PID regulator subject to tuning for desired response. \( F_X \) is the surge force, \( F_Y \) is the sway force and \( M_{\psi} \) is the yaw moment required by the motion controller.
2.3 Neural network control allocation

A NN was used to provide the transformation between desired generalized forces (input) and the individual thruster commands (output). More specifically the learning methodology adopted was that of the Extreme Learning Machine (ELM) introduced by Guang-Bin Huang et al. (2004). Two main approaches exist with regards to adapting structure and weight parameters of the network. The most basic one involves a single, initial, calculation of weights, either using a fixed structure or adapting the structure by means of pruning/constructive methods. Alternatively, one may update both structure and weights iteratively, termed online learning, to adapt the network to time-varying properties of the process which produces the data. In this paper we adopt the first approach, fixing the structure and the weights of the network initially. Furthermore, the ELM is capable of approximating any continuous target function given proper architecture and sufficient training data. This, along with the efficiency of the algorithm, motivated the choice of using a shallow network structure as opposed to a deep neural network. The learning process of the ELM is outlined below using the same notation as Huang et al. (2011).

We define two variations of the control allocation unit for comparison of performance. They differ only in terms of the structure of the NN allocator:

- Allocator 1: Only the generalized forces were applied as input to the network.
- Allocator 2: The input thrust command is augmented using the applied commands from the previous time step.

Allocator 1 As mentioned, the implementation of Allocator 1 used only the generalized force/moment vector issued from the motion controller as input. This is the common interface signal used by the methods referenced in the introduction. The output was the five individual command signals. To determine the proper hidden layer neuron number several different neuron numbers were tested. The neuron number corresponding to the lowest Root Mean Square Error (RMSE), based on validation by randomly selected input/target pairs of the entire training set, was selected. This approach yielded a NN structure of 3 input neurons, 20 hidden layer neurons and 6 output neurons. This mapping remained fixed for the duration of the test case given in section 3.2.

Allocator 2 As a means to add additional information about the rate changes experienced in the training set the input to the allocation unit was augmented. The new input consisted of the same generalized forces as in Allocator 1, in addition to the commands issued to each thruster at the previous time step. Otherwise the two allocation implementations (1 and 2) were identical. For both allocators a training set of 7800 samples was used.

3. SIMULATION RESULTS

Simulations were carried out in a commercial marine vessel simulator developed by the Norwegian company Offshore Simulator Centre (OSC) AS. Test case parameters are given in section 3.1.

3.1 Test case description

The vessel, shown in figure 2, was ordered to remain fixed at a position of (0,0) m in the NED reference frame and a heading angle of 0 degrees. To achieve this the vessel utilized 6 thrusters. The two stern-mounted main thrusters, which were operated in tandem, required a command of blade pitch angle (thrusters marked 5 and 6 in figure 2). Two sets of individually operated tunnel thrusters were located at the bow and stern of the vessel (thrusters marked 1-4 in figure 2). Both set of thrusters were operated using RPM commands. All thrusters were considered non-rotatable, producing positive thrust in the
Fig. 2. The vessel and its thruster layout. Note that the two leftmost thrusters (main thrusters) supply thrust in the positive/negative x-direction only.

Fig. 3. The position and heading of the vessel recorded during the test case run for both allocator 1 and 2.

Fig. 4. The commands input to each of the thrusters for the test case using allocator 1. Top: RPM commands issued to the bow tunnel thrusters. Middle: RPM commands to the stern tunnel thrusters. Bottom: Blade pitch angle commands issued to the two aft main thrusters.

3.2 Allocator 1

Figure 3 shows the performance of the complete system, which is to remain at a fixed location and heading. The red lines of figure 3 describe the performance of the system using allocator 1. The rapid change rate of this allocator allows it to compensate for the step change quickly and therefore minimize the deviation from the desired desired position. However, the red line of the middle plot of figure 3 reveals slow convergence in the East direction. The high-frequency overloaded signal seen in all plots in figure 3 is caused by the vessel interacting with waves.

Figure 4 shows the output from the allocation unit for allocator 1. It is evident that the commands generated by the allocation unit is very sensitive to variation in the generalized force command. This might suggest that further wave-filtering and controller tuning might be required for this implementation to be useful. The excessive changes in thruster commands are also visible in figure 5, showing the change in command between time steps and also the maximum change allowed for each thruster. The sampling frequency of the system was set to 20 Hz, yielding the rate limit in figures 5 and 7 based on table 1

3.3 Allocator 2

Allocator 2 is less aggressive relative to allocator 1, although the same parameters for the PID regulators have been used. The derived thruster commands change more...
and the wind velocity was set to increase from 4 m/s to position. Significant wave height was increased to 3 meters wind and wave direction was set to act from west to east to approach the maximum thrust limits for the thrusters. The 3.4 Magnitude constraint

Figure 7 shows the reduction in rate change due to the allocation in command rate of change. This allocator implementation result in a significant reduction in the convergence. The commands issued by thruster 1, the East direction (middle plot of figure 3) response slowly, yielding increased settling times. Similar to allocator 1, the East direction (middle plot of figure 3) response shows the slowest convergence. The commands issued by this allocator implementation result in a significant reduction in command rate of change.

Figure 7 shows the change rate of the commands issued to each thruster.

Figure 8 gives the corresponding thruster setpoint commands issued from the allocation unit. For this specific test Allocator 2 was used. The figure shows that the commands for thrusters 1-4 saturates, rendering the vessel underpowered in the lateral direction. Insufficient thrust force causes the vessel to drift off in the east direction (see the middle plot of figure 8) as well as failing to converge to a zero heading angle.

4. DISCUSSION

With an augmented input vector, the control allocation NN has been shown to provide constraint handling for rate change and magnitude of thrusters on a simulated vessel. Allocator 2 displays the most realistic implementation, adhering to the rate constraints present in the dataset used for training. It is therefore necessary to provide a training set that reflects the constraints of the vessel, meaning that to achieve the maximum rate change the thrusters on the vessel must be operated at its maximum rate when logging the training data. The use of thrust force measurements limits the applicability of this approach to simulators.

The test constructed to verify the ability of the NN allocator to deal with thruster magnitude constraints may
not represent conditions that will be faced by a real vessel. However, it pushes the NN allocation to its thresholds, showing that it is able to constrain the commands based on the dataset used for training the NN.

Although not verified in this paper, thruster failure scenarios may be handled by a re-training step of the NN allocation mapping. For the training set and NN architecture used in this paper, the entire re-training procedure is performed in 1.3 seconds. More sophisticated functionality such as power minimization, support for thrusters rotatable in the range $[-180, 180]$ degrees and support for forbidden zones of rotatable thrusters were not considered. They will be the aim for future improvements of the suggested approach.

5. CONCLUSION

In this paper we introduce a neural network thruster allocation scheme that only relies on thruster force and command measurements. Though systems onboard real vessels do not accommodate thrust force measurements, we seek here to promote an approach to control allocation that does not rely on knowledge about the specific thruster parameters. The augmented version of the neural network allocator is able to learn the relationship between the generalized thrust and thruster commands as well as handling maximum/minimum and rate constraints.

ACKNOWLEDGEMENTS

The authors would like to thank OSC for their support in relation to performing the simulation study.
