Acute physiological and perceptual responses to Brazilian jiu-jitsu sparring: The role of maximal oxygen uptake

Sparring is a training form in combat sports designed to simulate fighting. This study sought to assess the relationship between physiological and perceptual responses to Brazilian jiu-jitsu (BJJ) sparring and their relationship with maximal oxygen uptake ($V\text{O}_{2\text{max}}$). Twelve male BJJ athletes (age: 30.6 ± 2.7 (SD) years; height: 182.5 ± 5.9 cm; body mass ($m_b$): 81.2 ± 6.7 kg; body fat: 9.9 ± 3.2%) with 4.6 ± 2.2 years of BJJ experience and a training volume of 10.3 ± 4.4 hours·week$^{-1}$ participated in the study. Following a $V\text{O}_{2\text{max}}$ measurement, heart rate (HR), blood lactate concentration ($[\text{La}^-]$), and rating of perceived exertion (RPE) were obtained during sparring in a regular training session, with each participant sparring 5 consecutive 6-minute rounds separated by 90-second breaks. Mean sparring HR was 164 ± 9 beats·min$^{-1}$, equivalent to 85 ± 4% of the maximal HR (HR$_{\text{max}}$). The sparring was perceived as “hard”. Mass-independent $V\text{O}_{2\text{max}}$ correlated negatively with HR, relative HR (%HR$_{\text{max}}$), and $[\text{La}^-]$ in sparring. The negative relationship between $V\text{O}_{2\text{max}}$ and physiological markers of exertion suggest that $V\text{O}_{2\text{max}}$ affects exercise tolerance in BJJ and could also point to a limited efficacy of sparring for developing aerobic endurance due to insufficient exercise intensity in trained athletes.

Keywords: martial arts; grappling; combat sports; lactate; heart rate; RPE
Introduction

Brazilian jiu-jitsu (BJJ) is a grappling-based combat sport where the objective is positional control and ultimately a submission of the opponent via a chokehold or joint lock. Official matches can span from a few seconds to hours, but are commonly regulated for durations of 5 to 10 minutes (International Brazilian Jiu-Jitsu Federation, 2015). Due to the nature of the sport, directly measuring the oxygen cost of BJJ combat is not feasible. Thus, indirect markers of exertion such as heart rate (HR), blood lactate concentration ([La\(^-\)]\(_b\)), and rating of perceived exertion (RPE) have been used to investigate sport-specific demands (Andreato, Follmer, Celidonio, & Honorato, 2016). The latter has become an increasingly popular approach to intensity assessments in combat sports due to its association with physiological markers such as HR and [La\(^-\)]\(_b\) in both training and competition (Slimani, Davis, Franchini, & Moalla, 2017). In BJJ, however, the relationship between these markers is less clear. HR and [La\(^-\)]\(_b\) appears to correlate (Villar, Gillis, Santana, Pinheiro, & Almeida, 2018), while RPE does not have a consistent relationship with either (Andreato, Follmer, et al., 2016; Andreato et al., 2013; Andreato et al., 2012).

The energy demands of grappling is met by both aerobic and anaerobic processes (Ratamess, 2011). BJJ is characterized by a high volume of low-intensity work interspersed with brief, more intense efforts (Andreato, Follmer, et al., 2016). This places considerable demand on aerobic adenosine triphosphate resynthesis to sustain physiological performance. The degree of aerobic metabolism in grappling is also apparent from spiroergometer measurements during judo combat (Julio et al., 2017). The maximal aerobic metabolic rate during exercise is determined by the maximal oxygen uptake (\(\dot{VO}_2\)max). Recent investigations have reported a \(\dot{VO}_2\)max of approximately 50 ml·kg\(^{-1}\)·min\(^{-1}\) in BJJ athletes (Andreato, Lara, Andrade, & Branco, 2017; Ovretveit, 2018), which is similar to the age-matched general population (Edvardsen, Hansen, Holme, Dyrstad, & Anderssen, 2013) and slightly below that of wrestlers (Chaabene et al., 2017) and judokas (Franchini, Del Vecchio, Matsushigue, & Artioli, 2011). Observations from both simulated (Andreato, Julio, Panissa, et al., 2015; Andreato, et al., 2012; Da Silva et al., 2013; Villar, et al., 2018) and official (Andreato, et al., 2013; Andreato et al., 2014; Díaz-Lara, del Coso, García, & Abián-Vicén, 2015) BJJ competition show that athletes experience significant increases in [La\(^-\)]\(_b\), with levels often exceeding 10 mmol·L\(^{-1}\)
following a single match, indicating a considerable reliance on anaerobic energy supply. Although this can partly be ascribed to the intermittent nature of BJJ combat, it also implies a limited capacity for aerobic energy yield.

A high aerobic exercise intensity has been shown to be a key component for efficient improvements in \( \dot{V}O_{2\text{max}} \) (Bacon, Carter, Ogle, & Joyner, 2013; Helgerud et al., 2007; MacInnis and Gibala, 2017; Storen et al., 2017). A BJJ training session typically consists of warm-ups, technical drills, and sparring (Branco et al., 2016). Sparring is a form of fight simulation, often mirroring official competition rules and performed at a range of different intensities, including maximal effort. Since BJJ does not involve strikes to the head, sparring can be performed at a competition pace with little risk of serious head trauma, assuming a certain level of proficiency. Conversely, intense sparring in striking-based disciplines such as boxing can result in repetitive subconcussive and even concussive blows to the head, increasing the risk for neurological conditions such as chronic traumatic encephalopathy (McKee et al., 2009). Due to the comparably low risk of high-intensity sparring in BJJ, it is often used as a form of endurance training. However, the moderate \( \dot{V}O_{2\text{max}} \) in this population warrants investigating its role in BJJ training and whether sparring is an efficient approach to athlete conditioning.

To the best of the author’s knowledge, no study to date has explored the relationship between \( \dot{V}O_{2\text{max}} \) and training intensity in BJJ. The lacking association between BJJ training volume and \( \dot{V}O_{2\text{max}} \) suggest that BJJ might have limited utility for developing aerobic endurance (Ovretveit, 2018). Thus, the aim of this study was to determine the association between \( \dot{V}O_{2\text{max}} \) and acute physiological responses to unrestricted BJJ sparring, as measured by HR and [La\(^-\)]\(_b\). Additionally, the relationship between RPE and these physiological measurements was assessed. It was hypothesized that 1) \( \dot{V}O_{2\text{max}} \) would be negatively associated with HR and [La\(^-\)]\(_b\), and 2) that there would be a lack of relationship between the physiological markers of exertion and RPE.
Materials and methods

Study design

Athletes with a consistent volume, frequency, and form of training (≥ 3 sessions·week$^{-1}$ with a sparring component) were recruited from the largest BJJ academy in the region. A questionnaire was used to collect information on rank, experience, and training habits to assess eligibility. The participants underwent cardiopulmonary exercise testing (CPET) to determine their VO$_{2\text{max}}$. Subsequently, an upcoming BJJ training session was selected for each athlete for measurements of sparring intensity. No more than one participant was assessed per session to reduce the impact of external factors on the training. The number of sparring rounds was standardized and based on the average training volume of the participating athletes.

Each training session lasted 120 minutes and consisted of 60 minutes of warm-ups and technical drills, followed by 60 minutes of monitored sparring. The curriculum was overlapping from session to session and the physiological impact of any variation in technical content was controlled for with baseline measurements of [La$^-$]$_b$ (Lactate Scout+, SensLab GmbH, Germany), HR (M400, Polar Electro, Finland), and RPE (Borg, 1970). Then, the participant sparred 5 consecutive 6-minute rounds. Each round was separated by a 90-second break. During the break, measurements of [La$^-$]$_b$ and RPE were obtained, and HR data for the past round stored. The participants rotated randomly through opponents of different ranks (white through brown) ranging from light to super heavyweight. Partner selection was supervised to assure adequate variation and avoid duplicate pairs. The participants were instructed not to deviate from their normal style and intensity of sparring.

Participants

The study sample comprised 12 active male BJJ athletes (age: 30.6 ± 2.7 years; height: 182.5 ± 5.9 cm; body mass (m$_b$): 81.2 ± 6.7 kg; body fat: 9.9 ± 3.2%) ranked from white to brown belt, with 4.6 ± 2.2 years of experience and a BJJ training volume of 10.3 ± 4.4 hours·week$^{-1}$. Athletes had to be active competitors with > 1 year of consistent BJJ training or hold the rank of blue belt or higher to be eligible for participation. Additionally, sparring at unrestricted intensities had to be a part of their training and BJJ their main form of aerobic conditioning. Exclusion criteria were low training...
frequency (< 3 sessions·week⁻¹) and injuries that inhibited training intensity and/or the baseline CPET.

The study was approved by the local ethics committee. Written informed consent was obtained from each participant prior to participation.

**Anthropometry**

Stature was measured to the nearest 0.5 cm with a wall-mounted stadiometer (Seca Corp., Hanover, MD). Segmental multifrequency bioelectrical impedance analysis (MC-980-MA, Tanita Corp., Tokyo, Japan) was used to determine mass and composition of the body. The participants were instructed to avoid same-day exercise prior to testing and be in a euhydrated state with an empty bladder and bowel at the time of the test.

**Maximal oxygen uptake**

Oxygen uptake (\(\dot{V}O_2\)) was measured (SensorMedics Vmax Spectra 229d, Yorba Linda, CA, USA) during an incremental CPET on a motorized treadmill (PPS 55 Med, Woodway GmbH, Weil am Rhein, Germany) at a 3° gradient. After a standardized warm-up of 10 minutes at 7 km·h⁻¹, treadmill speed was increased by 1 km·h⁻¹ every minute until exhaustion, which generally occurred within 5 to 8 minutes. HR was continuously monitored (M400) and the maximal HR achieved was determined as \(HR_{max}\). The highest 30-second average \(\dot{V}O_2\) was calculated and accepted as \(\dot{V}O_{2max}\) if at least two of the following criteria were met: \(\dot{V}O_2\) levelling off despite increasing workload; a proximity of \(≤ 5\) beats·min⁻¹ to \(HR_{max}\) if this was known; respiratory exchange ratio \(≥ 1.1\); and/or \([La^-]_b ≥ 8\) mmol·L⁻¹.

Following the CPET, the subjective level of exertion was rated on Borg’s category scale (Borg, 1970), and blood was sampled from the fingertip and analysed (Biosen C-Line, EKF Diagnostics GmbH, Barleben, Germany) to determine \([La^-]_b\).

--Insert table 1 here--
**Allometric scaling**

To account for differences in body size, mass-independent $\dot{V}O_{2max}$ was calculated with the allometric equation $y \cdot x^b$, in which $y = \dot{V}O_{2max}$, $x = m_b$, and $b$ = the scaling exponent. The theory of similarity suggests that $\dot{V}O_2$ is proportional to $m_b^{2/3}$ (Astrand and Rodahl, 1986), but in running performance, $b = 0.75$ has been shown to be more appropriate (Helgerud, 1994). Thus, $\dot{V}O_{2max}$ was expressed in absolute ($L \cdot min^{-1}$), mass-relative (ml·kg$^{-1}$·min$^{-1}$), and mass-independent (ml·kg$^{-0.75}$·min$^{-1}$) values. Correlations between the expressions of $\dot{V}O_{2max}$ and $m_b$ were calculated, with the coefficient size and significance being used to estimate the degree of linear independence.

**Statistical analyses**

Statistical analyses were performed using IBM SPSS version 24 (Chicago, IL, USA). Figures were made with GraphPad Prism version 6 (San Diego, CA, USA). Normality was assessed with the Shapiro-Wilk test and quantile-quantile plots. Repeated measures analysis of variance with Fisher's Least Significant Difference post hoc test was used to analyse round-by-round changes in markers of exertion. Mauchly’s test was used to assess data sphericity, with the Greenhouse-Geisser correction being applied when appropriate. Pearson product-moment correlation coefficients were computed to determine the strength and direction of relationships between variables. Deltas for each round were calculated as the post-round value – pre-round value. Data are presented as mean ± standard deviation in tables and text, and mean ± standard error in figures. Statistical significance was accepted at $p < 0.05$. 
Results

All participants achieved $\dot{V}O_{2\text{max}}$ during the CPET without incidence (table 1) and successfully completed the monitored training session with no adverse events. Significant between-round differences were detected for HR ($F(2,22) = 194.22, p < 0.001, \eta^2 = 0.95$), relative HR ($\%HR_{\text{max}}$) ($F(2,23) = 193.42, p < 0.001, \eta^2 = 0.94$), $[\text{La}^-]_b$ ($F(5,45) = 29.40, p < 0.001, \eta^2 = 0.77$), and RPE ($F(5,55) = 42.70, p < 0.001, \eta^2 = 0.80$). Figure 1 shows the round-by-round physiological and perceptual responses to sparring. Mean and delta responses are presented in table 2 and table 3, respectively. Figure 2 illustrates a typical HR response to a round of sparring.

Body mass correlated with absolute $\dot{V}O_{2\text{max}}$ ($r = 0.660, p < 0.05$), while its relationship with mass-relative $\dot{V}O_{2\text{max}}$ was nonsignificant ($r = -0.225, p = 0.481$). The correlation coefficient between scaled $\dot{V}O_{2\text{max}}$ and $m_b$ was close to zero ($r = 0.058, p = 0.859$), indicating linear independence. Mass-independent $\dot{V}O_{2\text{max}}$ was negatively associated with mean HR ($r = -0.826, p < 0.001$), $\%HR_{\text{max}}$ (figure 3), and $[\text{La}^-]_b$ (figure 4). Furthermore, mean HR correlated with mean $[\text{La}^-]_b$ ($r = 0.677, p < 0.05$). Mean $\%HR_{\text{max}}$ correlated with mean $[\text{La}^-]_b$ ($r = 0.745, p < 0.01$), and negatively with $m_b$ ($r = -0.653, p < 0.05$). Rank was not associated with any expression of $\dot{V}O_{2\text{max}}$ nor sparring HR ($p > 0.05$), but tended to correlate negatively with mean $[\text{La}^-]_b$ ($r = -0.563, p = 0.056$). A similar, positive tendency was observed between mean RPE and mean $[\text{La}^-]_b$ ($r = 0.568, p = 0.054$). RPE and HR were generally independent, but a significant relationship was observed in the last round ($r = 0.642, p < 0.05$). No association between RPE and $\dot{V}O_{2\text{max}}$ was detected ($p > 0.05$).
Discussion

Despite an increasing number of studies investigating physiological and perceptual responses to competitive BJJ combat, little attention has been devoted to these responses in regular training. Exploring the interaction between sparring intensity and VO_{2max} may help discern the role of this attribute in BJJ combat, as well as the utility of sparring as an approach to athlete conditioning. Thus, this study sought to investigate the relationships between physiological and perceptual markers of exertion and VO_{2max} during unrestricted BJJ sparring. The main findings were that the athletes worked up to a high intensity during the first two rounds of sparring, which was maintained for the rest of the session, with an average HR of 85% of HR_{max}; accumulated significant amounts of lactate during the initial round of sparring with no meaningful reduction in subsequent rounds; and rated their average level of exertion as “hard”, equivalent to 74% of the maximal perceived exertion. VO_{2max} was negatively associated with sparring HR, %HR_{max}, and [La^{-}]_{b}, indicating that VO_{2max} might have an important impact on physiological performance in BJJ combat by delaying the fatigue process. Furthermore, given the importance of exercise intensity for improvements in VO_{2max}, these observations could imply that sparring does not effectively target this attribute, particularly in trained (> 55 ml·kg^{-1} (De Pauw et al., 2013)) athletes.

An increased VO_{2max} will improve intracellular oxygen availability during exercise, thus reducing the reliance on anaerobic processes and consequently the metabolite response to a given exercise intensity, enhancing the ability to maintain muscle pH and contractile capacity at higher intensities (Astrand and Rodahl, 1986; Ratamess, 2011). In addition to the potential effects on exercise tolerance in BJJ combat, this has relevance for tournaments, where progressing through a bracket is akin to an interval training session, with between-match rest periods of similar duration as the match regulation time (International Brazilian Jiu-Jitsu Federation, 2015). Shifting from anaerobic to aerobic energy yield could result in a considerable physiological performance advantage, particularly in large brackets. Interestingly, [La^{-}], has been observed to decrease with consecutive matches (Andreato, Julio, Panissa, et al., 2015), which could reflect an inability to maintain work output due to a depletion of phosphocreatine, proton accumulation, and reduced pH (Gastin, 2001). Although the present findings do not establish a causal link between VO_{2max} and sparring intensity, the strong negative
correlation between $\text{VO}_{2\text{max}}$ and the physiological markers of exertion indicate that this attribute can have considerable impact on BJJ performance.

The nature of the relationship between $\text{VO}_{2\text{max}}$ and $\%\text{HR}_{\text{max}}$ also offers support to the previously proposed ceiling effect of BJJ on developing this attribute significantly beyond the population average (Ovretveit, 2018). The average sparring HR suggests that the athletes performed at an intensity conducive to cardiovascular improvements (Storen, et al., 2017). This, however, was not reflected in their $\text{VO}_{2\text{max}}$, which was moderate compared to other athlete populations (Saltin and Astrand, 1967), despite regularly engaging in high-intensity sparring. Similar limitations have been observed in soccer, albeit in athletes with a higher $\text{VO}_{2\text{max}}$. In a study on soccer-specific aerobic endurance training, Hoff and colleagues (2002) observed that, while sport-specific training can be a useful approach to improvements in aerobic endurance, players with the highest $\text{VO}_{2\text{max}}$ performed at the lowest fraction of $\text{VO}_{2\text{max}}$ during small group play. This highlights the importance of careful considerations when applying sport-specific training to improve physiological functions. In the current BJJ literature, a $\text{VO}_{2\text{max}}$ considerably above 50 ml·kg$^{-1}$·min$^{-1}$ is rarely observed (Andreato, et al., 2017; Ovretveit, 2018). In fact, the present athletes were in the higher range of what is typically found in this population, and thus might be in proximity of the upper limit of $\text{VO}_{2\text{max}}$ achievable through BJJ training alone.

The effort pattern of BJJ combat has been thoroughly analysed (Andreato, Follmer, et al., 2016), with several investigations providing physiological context to these observations (Andreato, et al., 2013; Andreato, Julio, Panissa, et al., 2015; Andreato, et al., 2014; Andreato, et al., 2012; Da Silva, et al., 2013; Diaz-Lara, et al., 2015; Villar, et al., 2018). Yet, there is a dearth of continuous HR measurements and consequently a knowledge gap regarding this marker of intensity in BJJ. The high variation in metabolic demand necessitates constant monitoring of HR during combat to obtain a representative measurement. This was evident from the individual HR curves observed in the present study, which revealed considerable fluctuations during rounds. Although some practical concerns regarding the use of a HR monitor in combat sports have been raised (Slimani, et al., 2017), results from the present study suggest that it can be a feasible instrument for intensity measurements in BJJ. In similar studies, HR has been obtained pre- and post-combat (Andreato, Julio, Panissa, et al., 2015;
Andreato, et al., 2012; Villar, et al., 2018). While this data can be indicative of effort, continuous measurements of HR expressed relative to the individual HRmax provides a more accurate description of intensity.

Despite being a practical tool for intensity assessments, HR data obtained in combat sports comes with several important caveats (Slimani, Znazen, Sellami, & Davis, 2018). When a given rate of continuous work is performed for > 2 minutes, HR can be used as an indicator of VO2 (Swain, Abernathy, Smith, Lee, & Bunn, 1994). However, HR during intermittent work of < 2 minutes can overestimate VO2 (Hoff and Helgerud, 2004). Thus, since BJJ combat typically consists of short work periods with frequent changes in intensity (Andreato, Follmer, et al., 2016), sparring HR is likely not an accurate representation of sparring VO2. Moreover, HR is elevated in arm compared to leg exercise at a given workload (Vokac, Bell, Bautz-Holter, & Rodahl, 1975), which is relevant to BJJ, where the arms are heavily involved. This can be exacerbated by isometric muscle contractions, which increases blood pressure and consequently HR. Additionally, both simulated and official BJJ competition have been shown to induce a stress hormone response (Moreira et al., 2012), possibly leading to further increases in HR. Conversely, circulatory alterations related to supine exercise can reduce both submaximal and maximal HR (Cotsamire, Sullivan, Bashore, & Leier, 1987), which might counteract some of the factors causing an overestimation. However, the notion that sparring HR was overestimated in the present study is supported by the disagreement between RPE and HR, with the average relative HR being 15% higher than the relative RPE.

The discrepancy between RPE and HR suggests that RPE should be used with caution in BJJ, as previously expressed by others (Andreato, Follmer, et al., 2016; Andreato, Julio, Goncalves Panissa, et al., 2015). Yet, interestingly, mean RPE and [La−]b tended to correlate. Thus, RPE might provide some indication of physical exertion during sparring. However, as the literature contains conflicting findings (Andreato, et al., 2013; Andreato, et al., 2012; Villar, et al., 2018), the applicability of RPE in BJJ is still debatable. Notably, the observed RPE and lactate responses in the present study were comparable to those found in athletes continuously encouraged by coaches and instructed to perform at the highest possible intensity (Branco, et al., 2016). This suggest a high voluntary effort, as the athletes were specifically instructed not to deviate from their normal training.
intensity. The short 90-second breaks might have increased perceived and actual exertion, but underestimated \([\text{La}^-]_b\) due to a lag in lactate diffusion from the working muscles to systemic circulation. Generally, round-by-round variations in the physiological responses were low compared to similar experiments with longer breaks (Andreato et al., 2016; Andreato, Julio, Panissa, et al., 2015). Interestingly, RPE peaked after the last round, which could reflect a lack of recovery between rounds and the cumulative effects of periodic work above the anaerobic threshold.

Consistent with past findings (Andreato, et al., 2017; Ovretveit, 2018), rank was not associated with \(\dot{V}O_{2\text{max}}\), nor did it correlate with sparring HR. However, it tended to have a negative relationship with \([\text{La}^-]_b\). Previously, it has been suggested that differences in BJJ-specific endurance can in part be attributed to work economy (Ovretveit, 2018). A more advanced athlete might be able to perform techniques at a lower energy cost and rely less on prolonged isometric muscle contractions during sparring, thus improving local blood flow. Aspects related to work economy can likely be modified substantially by sport-specific training. Important to note, however, is that \(\dot{V}O_{2\text{max}}\) and work economy are separate determinants of aerobic endurance performance and should be trained accordingly (Pate and Kriska, 1984).

The impact of \(m_b\) on athletic performance is related to the extent gravity is counteracted by the athlete (Hoff, Kemi, & Helgerud, 2005). The importance of allometric scaling in size-heterogeneous samples is well-established (Astrand and Rodahl, 1986; Bergh, Sjodin, Forsberg, & Svedenhag, 1991; Hoff, et al., 2005; Lolli, Batterham, Weston, & Atkinson, 2017). In the present study, there was a \(< 29\%\) weight difference among the participants, and normalisation using the exponent 0.75 resulted in a mass-independent \(\dot{V}O_{2\text{max}}\). Ideally, the scaling exponent should be based on how the oxygen demand relates to \(m_b\) in the specific activity. However, the influence of \(m_b\) on \(\dot{V}O_2\) during grappling is difficult to gauge due to the high positional variation and unfeasibility of sport-specific spiroergometry.

Standing combat, similar to wrestling and judo, requires full support of \(m_b\), while groundwork presents numerous ways of which \(m_b\) is carried. Parenthetically, \(m_b\) likely affects pass- and guard-focused grappling differently. Regardless of grappling style, \(m_b\) will inevitably have some impact on performance; the lack of a sport-specific scaling exponent does not negate the principles of allometry. A negative association was observed between \(m_b\) and \(\%HR_{\text{max}}\), which could be related to a greater
absolute capacity for oxygen consumption combined with a grappling style that minimizes the impact of \( m_b \) in the bigger athletes. However, \( m_b \) did not significantly relate to \([\text{La}^-]_b\), which suggest a limited impact of the ostensibly lower sparring intensity in these athletes. The reduced relative HR could have been caused by factors such as fewer and/or shorter isometric contractions, techniques that replaced muscular work with mechanical advantages, pressure rather than speed when passing the guard, and/or less scrambling. It could also simply have been a result of the size advantage held by the bigger athlete as the sample was not separated into weight classes. In official competition facing size-matched opponents, the intensity profile might be different. Thus, \( m_b \) is likely not intrinsically linked to lower combat intensity, but rather more dependent on the size relationship between the combating athletes.

Two distinct intensity components of a typical BJJ training session emerged from this study. Warm-up and skill training represented low-intensity work, with a mean \([\text{La}^-]_b\) < 2 mM and HR < 50% of \( \text{HR}_{\text{max}} \) after an hour of drilling techniques. The participants rated their level of exertion as “very, very light” pre-sparring. Notably, 12 separate training sessions with overlapping, but slightly varying content were monitored and all elicited similar HR, lactate, and RPE responses, indicating that physical exertion when performing BJJ drills is largely independent of the specific technique being emphasized. Contrasting the low-intensity skill component was the sparring, which represented high-intensity work, perceived by the athletes as “hard”, with a mean \([\text{La}^-]_b\) of ~9 mM and mean HR of 85% of \( \text{HR}_{\text{max}} \).

As opposed to similar investigations, where markers of exertion have been assessed during official competitions (Andreato, et al., 2013; Andreato, et al., 2014; Diaz-Lara, et al., 2015) or in study designs simulating them (Andreato, Julio, Panissa, et al., 2015; Andreato, et al., 2012; Da Silva, et al., 2013; Villar, et al., 2018), this study did not attempt to recreate a competition setting. Rather, acute physiological and perceptual responses to BJJ sparring was assessed during a regular training session. The additional cardiorespiratory information provided by \( \dot{V}_{\text{O}_2}\text{max} \) and continuous HR measurements represents a novel approach to understanding the type and degree of exercise stimulus in BJJ. The generalizability of the present findings is limited by the sample size and the cross-sectional study design, which cannot establish causality. Studies involving more participants and repeated
measurements of physical capacities and physiological responses to sparring may provide further insight into the acute and chronic effects of BJJ training.

Conclusions

The negative relationship observed between VO\textsubscript{2max} and physiological markers of exertion suggest that VO\textsubscript{2max} affects exercise tolerance in BJJ. This could also imply a limited efficacy of sparring for the development of VO\textsubscript{2max} due to insufficient exercise intensity in trained athletes. Although the athletes appeared to self-select a high sparring intensity, HR data obtained during BJJ combat should be interpreted with caution, as it might overestimate actual exercise intensity and energy expenditure. An increased VO\textsubscript{2max} appears to be associated with a reduced reliance on anaerobic processes during sparring, which could have implications for the sustainability of both match and tournament performance. Considering that BJJ is a skill-based sport, BJJ training should represent the bulk of the athletes’ training volume. Although this training likely induces improvements in some aspects of aerobic endurance, like work economy, it might have a limited effect on others, such as VO\textsubscript{2max}, possibly related to effort characteristics and body position (Ovretveit, 2018). Thus, alternative approaches to aerobic conditioning should be considered by athletes who seek improvements in VO\textsubscript{2max}.
